INTRODUCTION

Mechanical ventilation is the process of using a device (ventilator) to support, partially or totally the delivery of gas to the lungs. The desired effect of mechanical ventilation is to maintain adequate levels of PO_2 and PCO_2 in arterial blood while also unloading the inspiratory muscles. Although negative-pressure chambers or wraps might fulfill this definition, this discussion focuses on the use of devices that use positive airway pressures.

Positive-pressure mechanical ventilation is used widely. In the United States, about 1 to 3 million patients annually are estimated to receive mechanical ventilatory support outside the operating room.¹ Traditionally, this support has been provided in *intensive care unit* (ICU) settings, but there are clear trends toward expanding the venues to subacute facilities, long-term care facilities, and the home. As the number of elderly increases and as more aggressive surgical and immunosuppressive therapies are developed, the need for mechanical ventilation in all of these venues is likely to increase.¹ In addition, increasing concerns about widespread outbreaks of respiratory pandemics has led many government agencies to stockpile large numbers of mechanical ventilators.²

POSITIVE-PRESSURE MECHANICAL VENTILATOR DESIGN FEATURES**GAS DELIVERY SYSTEMS****Positive-Pressure Breath Controller**

Most modern ventilators utilize piston/bellows systems, turbines, or controllers of high-pressure sources to drive gas flow.^{3,4} Tidal breaths are generated by this gas flow and can either be controlled entirely by the ventilator or be interac-

tive with patient efforts. Pneumatic, electronic, or micro-processor systems provide for various breath types. In general, these can be classified by what initiates the breath (trigger variable), what regulates gas delivery during the breath (target or limit variable), and what terminates the breath (cycle variable).^{5,6}

Breath triggers are generated by either a change in pressure or flow initiated by patient effort (assisted/supported breath) or by a set time (controlled breath). During the breath, gas delivery is regulated to meet a target or limit variable, which is generally either a set flow or a set inspiratory pressure. The breath is then terminated by a cycle variable, which can either be a set volume, a set inspiratory time, or a set flow. A high-pressure cycle variable is usually also present to limit lung over distention. [Figure 101-1](#) uses this classification scheme to describe the five most common breath types available on the current generation of ventilators: *volume assist* (VA), *volume control* (VC), *pressure assist* (PA), *pressure control* (PC), and *pressure support* (PS).

Mode Controller/Feedback Systems

The availability and delivery logic of different breath types define the “mode” of mechanical ventilatory support.^{3,5,6} The mode controller is an electronic, pneumatic, or microprocessor-based system that is designed to provide the proper combination of breaths according to set algorithms and feedback data (conditional variables) ([Table 101-1](#)).

The simplest mode is *assist-control ventilation* (ACV), which can provide either flow-targeted volume-cycled breaths (*volume assist-control ventilation* [VACV]) or pressure-targeted time-cycled breaths (*pressure assist-control ventilation* [PACV]). A simple feedback system is employed with ACV that guarantees a set number of positive-pressure breaths. If the patient’s underlying respiratory rate exceeds this guarantee, all breaths are patient-triggered breaths (VA or PA breaths). If the patient’s respiratory rate is below this guarantee, the ventilator will “make up the difference” with mandatory (controlled) breaths (VC or PC breaths).

Figure 101-1 Circuit pressure, flow, and volume tracings over time depicting the five basic breaths available on most modern mechanical ventilators. Breaths are classified by the variables that determine the trigger (machine time or patient effort), target/limit (t_i , set flow or set pressure), and cycle (set volume, set time, or set flow). The solid lines represent set or independent responses, and the dashed lines represent dependent responses. In all of these breaths, pressure is usually a “backup” cycle variable designed to terminate gas delivery if circuit pressure rises above an alarm limit.

Table 101-1 Breath Types Available on Common Modes of Mechanical Ventilation*

Mode	BREATH TYPES AVAILABLE [†]					
	VC	VA	PC	PA	PS	Sp
Volume assist—control	X	X				
Pressure assist—control			X	X		
Volume SIMV	X	X			X	X
Pressure SIMV			X	X	X	X
Pressure support					X	

*In addition to the five “basic” breaths depicted in Figure 101-1, this table also includes spontaneous unassisted/unsupported breaths.

[†]VC, volume control; VA, volume assist; PC, pressure control; PA, pressure assist; PS, pressure support; Sp, spontaneous unassisted. SIMV, synchronized intermittent mandatory ventilation.

Another relatively simple mode is *synchronized intermittent mandatory ventilation* (SIMV), which can provide either flow-targeted volume-cycled breaths (volume SIMV) or pressure-targeted time-cycled breaths (pressure SIMV). Like ACV, SIMV guarantees a set minimal number of positive-pressure breaths. Unlike ACV, however, if the patient’s respiratory rate exceeds this guarantee, the ventilator will provide assisted breaths up to the set rate and then allow unassisted (simple SIMV mode) or flow-cycled pressure support breaths (SIMV + PS mode) thereafter. If the patient’s respiratory rate is below the set guarantee, the ventilator will again “make up the difference” with mandatory (controlled) breaths. Note that although PS breaths are often provided during SIMV, PS breaths can also be provided as a stand-alone mode without any guaranteed breaths (pressure support ventilation). Importantly, many modern systems also have algorithms to generate breaths when an

apnea is detected; this represents a safety feature for modes with either low or no set guaranteed rates in case patient respiratory efforts are suddenly reduced or absent.

In recent years, more sophisticated feedback systems have been developed for these basic modes and are now available on many modern devices. These include *pressure-regulated volume control* (PRVC), *volume support* (VS), and *adaptive support ventilation* (ASV).

PRVC (also known by proprietary names such as “VC+,” “Autoflow,” and others) is an assist-control PACV that uses tidal volume as a feedback control for continuously adjusting the pressure target.⁷ The clinician sets a tidal volume target, and the ventilator then automatically sets the inspiratory pressure within a clinician-set range to achieve this goal.

VS is also based on a feedback design using patient-triggered, pressure-targeted, flow-cycled PS breaths. If a patient’s respiratory drive exceeds the clinician-set guaranteed rate, some PRVC systems will provide additional patient-triggered, time-cycled PRVC breaths while others will provide patient-triggered flow-cycled VS breaths. It is important to note that, with both PRVC and VS breaths, an improvement in respiratory mechanics will result in a lower applied inspiratory pressure, whereas a worsening in respiratory mechanics will result in a higher applied inspiratory pressure. Similarly, increasing respiratory effort by the patient will result in a lower applied inspiratory pressure, whereas decreasing respiratory effort by the patient will result in a higher applied inspiratory pressure.

ASV is also an assist-control, pressure-targeted, time-cycled mode of ventilation PACV that utilizes respiratory system mechanics to set the tidal volume-frequency pattern.⁸ The clinician sets only a desired minute ventilation and patient weight (for estimating anatomic dead space). Using controlled breaths, ASV initially calculates

resistance and compliance, as well as the expiratory time constant (resistance \times compliance). The ASV algorithm then adjusts the frequency–tidal volume pattern to minimize ventilator work (integral of pressure over volume) and thus conceptually to minimize applied forces to the lungs. The breathing pattern is also modulated by incorporating the expiratory time constant to avoid air trapping. As respiratory mechanics change, the frequency–tidal volume pattern is automatically adjusted to maintain minimal ventilatory work. In contrast, if patient efforts are triggering breaths with ASV, it behaves much like VS.

SUBSYSTEMS OF MECHANICAL VENTILATORS

Effort (Demand) Sensors

Current ventilators have sensors that detect patient effort, thus allowing for a number of interactions between the patient and the ventilator.^{9–11} Examples include patient-triggered breaths in which the ventilator initiates flow in response to patient demand and pressure-targeted/limited breaths in which the ventilator adjusts flow in response to patient demand (see “[Patient-Ventilator Interactions](#)” later). These sensors are usually either pressure or flow transducers in the ventilatory circuitry and are characterized by their *sensitivity* (the circuit pressure or flow change needed to initiate a ventilator response) and their *responsiveness* (the time needed to provide this response).¹²

Gas Blenders

Blenders mix air and O₂ to produce a *fractional concentration of O₂ in inspired gas* (FiO₂) ranging from 0.21 to 1.0. On newer systems, blenders are also available for other gases such as heliox, *nitric oxide* (NO), and anesthetic agents.

Humidifiers

With the upper airway bypassed by tracheal intubation, sufficient heat and moisture must be added to the inspired gas mixtures to avoid mucosal desiccation. *Active* humidifiers utilize external water sources and electrical power to adjust blended gas mixtures to near body conditions (tracheal temperature of $> 35^\circ\text{C}$, water content of $> 40\text{ mg/L}$).¹³ Heated wire circuits help facilitate this by preventing condensation and “rainout” in the ventilator tubing. *Passive* humidifiers use simple heat/moisture exchange devices in the ventilator circuit that reutilize heat and moisture trapped from expired gas. These disposable units can usually supply adequate heat and moisture (i.e., $> 30^\circ$ to 33°C and > 28 to $32\text{ mg/L H}_2\text{O}$) for many patients, particularly those receiving mechanical ventilation for only short periods of time.¹³

Expiratory Pressure Generator

Positive end-expiratory pressure (PEEP), or positive airway pressure throughout expiration, can be generated to help maintain alveolar patency and improve *ventilation-perfusion* (\dot{V}/\dot{Q}) matching (see “[Physiologic Effects of Positive-Pressure Mechanical Ventilation](#)” later). PEEP is usually applied by regulating pressure in the expiratory valve of the ventilator system but can also be applied by providing a continuous flow of source gas during the expiratory phase. Some expiratory valves have measurable resistance even when fully

open; this may result in inadvertent PEEP.¹⁴ As discussed in more detail later, a positive alveolar pressure may be present at end expiration if the expiratory time is inadequate for the lung to return to its “resting volume” or if significant flow limitation exists. Such inadvertent PEEP is referred to as *intrinsic PEEP* (PEEP_i), or as “auto-PEEP,” “occult PEEP,” or “air trapping.”¹⁵

Gas Delivery Circuit

The circuit linking the ventilator to the patient usually consists of flexible tubing that often contains pressure or flow sensors, closed suctioning systems, and an exhalation valve. It is important to remember that, because this tubing has measurable compliance (2 to 4 mL/cm H₂O are representative values), high circuit pressures may induce significant amounts of delivered gas to distend the circuitry rather than to enter the patient’s lungs.

Patient–Ventilator Circuit Interface

Positive-pressure ventilation is usually delivered through a tube inserted into the patient’s airway (orotracheal or nasotracheal tube or tracheostomy). These tubes generally have air-filled balloons, which are inflated to provide a proper airway seal. An alternative to the tracheal tube is a mask system. Both full-face and nasal masks have been utilized with a variety of ventilatory support systems and modes.¹⁶ Leaks around masks, however, can be significant and thus ventilatory support modes using masks must be able to provide adequate volumes and proper inspiratory timing. To this end, special mask ventilators with pressure-targeted and either time-cycled or leak-compensated, flow-cycled capabilities have been developed.¹⁶

Aerosol Generators (see Chapter 11)

Therapeutic aerosols (e.g., bronchodilators, steroids, vasodilators, antibiotics) can be delivered through the ventilator circuitry¹⁷ either by in-line nebulizers or by special adapters designed for metered-dose inhalers. Lung deposition is generally less in an intubated than in a nonintubated patient because the endotracheal tube serves as a significant barrier to aerosol delivery. Higher dosing is thus advisable.

The location of the aerosol generator in the ventilator circuit can affect deposition. The optimal site appears to be in the inspiratory limb several centimeters proximal to the patient’s “wye” connector.¹⁷ This location allows either nebulized medications or a metered-dose actuation to “charge” the inspiratory limb of the circuit during exhalation. Aerosol particle velocity is also slowed and becomes the leading portion of the next inspiration, both of which facilitate delivery.

Monitors and Graphic Displays

Although electronic and microprocessor-based systems have considerable internal monitoring of electronic and pneumatic function, the three variables generally displayed for clinical use are circuit pressures, flows, and volumes.¹⁸ Pressure sensors in the esophagus to estimate pleural pressures are also available.¹⁹ Alarms can be utilized on all of these monitors.^{6,20} Importantly, trending capabilities for up to 72 hours or more are now available on many modern systems. Most modern positive-pressure ventilators also

have oxygen sensors in the circuitry to ensure that the desired FIO_2 is being delivered. In addition, some ventilators may also have analyzers for measuring exhaled carbon dioxide and inhaled therapeutic gases such as NO or heliox.

PHYSIOLOGIC EFFECTS OF POSITIVE-PRESSURE MECHANICAL VENTILATION

VENTILATION AND RESPIRATORY SYSTEM MECHANICS (see Chapter 5)

Alveolar Ventilation and the Equation of Motion

Alveolar ventilation is the term for the delivery of fresh gas to the gas exchange regions of the lungs. Mathematically, this is expressed as:

$$\dot{V}_A = f \times (V_T - V_D)$$

where \dot{V}_A = alveolar ventilation, f = breathing frequency, V_T = tidal volume, and V_D = wasted ventilation or dead space. \dot{V}_A needs to be adequate to eliminate the carbon dioxide production (\dot{V}_{CO_2}) while maintaining a reasonable arterial PCO_2 (and pH) according to the following relationship:

$$\text{PaCO}_2 = (\dot{V}_{\text{CO}_2} / \dot{V}_A) \times 800$$

The lungs are inflated by mechanical ventilation when pressure and flow are applied at the airway opening. These applied forces overcome respiratory system compliance (both lung and chest wall components), airway resistance, and respiratory system inertance and lung tissue resistance to effect gas flow.^{21,22} For simplicity, because inertance and tissue resistance are relatively small, they can be ignored yielding the simplified equation of motion:

$$\text{Driving pressure} = (\text{flow} \times \text{resistance}) + (\text{volume} / \text{system compliance})$$

In the mechanically ventilated patient, this relationship is expressed as:

$$\Delta P_{\text{cir}} + \Delta P_{\text{mus}} = (\dot{V} \times R) + (V_T / \text{CRS})$$

where ΔP_{cir} is the change in ventilator circuit pressure above baseline (peak pressure minus set end-expiratory pressure: $P_{\text{peak}} - \text{PEEP}$); ΔP_{mus} is patient inspiratory muscle pressure generation (if present); \dot{V} is the flow into the patient's lungs; R is the resistance of the circuit, artificial airway, and natural airways combined; V_T is the tidal volume; and CRS is the respiratory system compliance. If there is PEEP_i , it must be overcome by muscle and circuit pressure before flow and volume can be delivered and thus PEEP_i will add to the driving pressure requirement.

During an inspiratory hold at end-inspiration in a patient who is not making respiratory efforts (i.e., no-flow condition: $\dot{V} = 0$, $P_{\text{mus}} = 0$), the ventilator circuit pressure “plateaus” at a pressure commonly referred to as the *plateau pressure* (P_{plat}). In this way, the components of P_{cir} can be determined. Specifically, the difference in P_{cir} during flow and during no-flow (the “peak to plateau difference”) allows for a calculation of total inspiratory resistance:

$$R = (P_{\text{peak}} - P_{\text{plat}}) / \dot{V}$$

Also, when $\dot{V} = 0$ at end-inspiration, $P_{\text{plat}} - \text{PEEP}$ allows calculation of the static respiratory system compliance:

$$\text{CRS} = V_T / (P_{\text{plat}} - \text{PEEP})$$

Separating chest wall and lung compliance (CCW and CL , respectively) requires measurement of *esophageal pressure* (P_{es}) to estimate pleural pressure.^{22a} With this measurement, the inspiratory change in P_{es} (ΔP_{es}) can be used in the following calculations:

$$\text{CCW} = V_T / \Delta P_{\text{es}}$$

$$\text{CL} = V_T / (P_{\text{plat}} - \text{PEEP} - \Delta P_{\text{es}})$$

In clinical practice, because CCW is usually quite high and ΔP_{es} is thus quite low, P_{plat} alone is often taken as an approximation of end inspiratory lung-distending pressure. However, there are many situations in which there is a stiff chest wall and this crude approximation is not valid (e.g., obesity, *acute respiratory distress syndrome* [ARDS], ascites, surgical dressings). Under these situations, the impact of a stiff chest wall must be considered when using these measurements to assess lung stretch.^{19,23,24}

Flow-Targeted Versus Pressure-Targeted Breaths

There are two basic approaches to delivering positive-pressure breaths: flow targeting and pressure targeting (see Fig. 101-1).^{3,5} With flow targeting (breaths 1 and 2 in Fig. 101-1), the clinician sets the inspiratory flow; circuit pressure is then the dependent variable. With pressure targeting (breaths 3 through 5 in Fig. 101-1), the clinician sets an inspiratory pressure target (with either time or flow as the cycling criterion); flow and volume are then the dependent variables (i.e., varying with the lung mechanics and patient effort). With a flow-targeted breath, changes in compliance, resistance, or patient effort will change P_{cir} (but not flow); in contrast, with a pressure-targeted breath, similar changes in compliance, resistance, or effort will cause a change of tidal volume (but not P_{cir}) (see dashed lines in Fig. 101-1).

Each strategy has advantages.²⁵ For flow-targeted breaths, a minimal tidal volume is guaranteed. For pressure-targeted breaths, the rapid initial flow and subsequent adjustable flow of pressure targeting may enhance gas mixing and patient synchrony (see discussions “[Distribution of Ventilation](#)” and “[Patient-Ventilator Interactions](#)” later).

Pressure-targeted breaths can also be modified with a volume feedback feature described earlier for PRVC and VS breaths to combine the enhanced gas mixing and patient-ventilator synchrony effects of a pressure-targeted breath with a certain volume guarantee. However, it is important to realize that providing a volume guarantee negates the pressure-limit feature set by the clinician because, with PRVC/VS, worsening respiratory system mechanics will drive applied pressures up. Another potential problem with PRVC/VS is that it may not adequately unload the patient if patient effort inappropriately increases due to pain or anxiety.²⁶

PEEP_i and the Ventilatory Pattern

PEEP_i is the positive alveolar end-expiratory pressure that arises because of inadequate expiration, caused by either inadequate expiratory time or airway collapse during expiration (or both). PEEP_i increases with increased minute

Figure 101-2 The distribution of ventilation in lung models with heterogeneous mechanical properties. Models of the lung are shown as two units with homogeneous mechanical properties (normal): (A) with abnormal compliance distribution (low regional lung compliance [CL]) and (B) abnormal resistance distribution (high regional airway resistance [RAW]). Note that in situations with heterogeneous lung mechanics, positive-pressure breaths are preferentially distributed to “healthier” regions of the lung and can produce regional overdistention—even when a normal-sized tidal volume is delivered. Note that in the obstructed example (high regional RAW), the overdistention may be transitory as gas moves from the low-resistance to the high-resistance unit over time (*pendelluft*). (Redrawn from MacIntyre NR: Mechanical ventilatory support. In Dantzker D, MacIntyre NR, Bakow E, editors: *Comprehensive respiratory care*. Philadelphia, 1995, WB Saunders, p 453.)

ventilation, decreased expiratory time fraction, and the increased respiratory system expiratory time constant (the product of resistance and compliance).²⁷

The development of PEEP_i will have different effects on flow-targeted compared with pressure-targeted ventilation. In flow-targeted ventilation, the constant delivered flow and volume (and thus ΔP_{cir}) in the setting of a rising PEEP_i will increase both the P_{peak} and the P_{plat} . In contrast, in pressure-targeted ventilation, the set P_{cir} limit coupled with a rising PEEP_i level will decrease ΔP_{cir} and thus the delivered tidal volume (and minute ventilation). Importantly, this may help limit the build-up of PEEP_i.

In the patient without respiratory effort, PEEP_i can be recognized in two ways. First, when PEEP_i is produced by an inadequate expiratory time, analysis of the flow graphic will show that expiratory flow has not returned to zero before the next breath is given. Second, PEEP_i in alveoli with patent airways can be quantified during an expiratory hold maneuver that permits equilibration of the PEEP_i with P_{cir} .²⁷

In the patient with active respiratory effort, PEEP_i can be assumed to be present if the expiratory flow has not reached zero before the next breath begins. However, the expiratory hold maneuver cannot be interpreted in an actively breathing patient. As noted in more detail later, in an actively breathing patient, PEEP_i can function as an inspiratory threshold load. This is best quantified by using P_{es} to estimate pleural pressures. With this technique, the change in P_{es} before a change in P_{cir} is a reflection of the threshold load imposed by PEEP_i (see “[Patient-Ventilator Interactions](#)” later).

Distribution of Ventilation

A positive-pressure tidal breath must be distributed among the millions of alveolar units in the lung.^{28,29} Factors affecting this distribution include patient-related factors: regional resistances, compliances, and functional residual capacities. Breaths will tend to distribute more to units with high

compliance and low resistance and away from obstructed or stiff units (Fig. 101-2A, Low Regional CL). This creates the potential for regional overdistention of healthier lung units, even in the face of “normal”-sized tidal volumes (see “[Ventilator-Induced Lung Injury](#)” later).

The flow pattern set on the ventilator may also affect ventilation distribution. For example, when there are marked inhomogeneities in airway resistance, slow and constant flows will tend to distribute gas more evenly (although consequent shorter expiratory times may worsen air trapping).²⁸ In addition, inspiratory pauses can also allow *pendelluft* action to fill slowly filling alveoli (Fig. 101-2B, High Regional RAW). In contrast, when there is parenchymal lung injury with minimal inhomogeneities in airway resistance, initially rapid flows with subsequent deceleration (typically seen in pressure-targeted breaths) may distribute gas more evenly and will pressurize lung units rapidly, producing a higher mean inspiratory alveolar pressure for a given breath volume.³⁰

It should be noted that more uniform ventilation distribution does not necessarily mean better \dot{V}/\dot{Q} matching (i.e., more homogeneous ventilation distribution may actually worsen \dot{V}/\dot{Q} matching in a lung with inhomogeneous perfusion). Because of all these considerations, predicting which flow pattern will optimize ventilation-perfusion matching is difficult and often requires trial and error.

ALVEOLAR RECRUITMENT AND GAS EXCHANGE

Because of alveolar flooding, inflammatory exudates, and collapse, parenchymal lung injury leads to \dot{V}/\dot{Q} mismatching and shunts.³¹ In many (but not all) of these disease processes, substantial numbers of collapsed alveoli can be recruited during a positive-pressure ventilatory cycle.³²⁻³⁵ Additional recruitment can sometimes be provided with the use of formal recruitment maneuvers or prolongation of inspiratory time.^{36,37} The application of PEEP is designed to prevent derecruitment during exhalation.

Recruitment Maneuvers

Recruitment maneuvers (RMs) can be performed using sustained inflations (e.g., 30 to 40 cm H₂O) for up to 30 to 120 seconds, by transient elevations of the PEEP-tidal volume settings, and by single or multiple “sighs” that take the lung briefly to near total lung capacity.³⁶ To avoid patient inspiratory or expiratory efforts, additional sedation or even neuromuscular blockade may be used. Importantly, RMs can have adverse hemodynamic consequences; close monitoring of the patient is mandatory during RMs. RMs provide initial alveolar recruitment only—maintenance of recruitment requires setting PEEP appropriately to prevent subsequent derecruitment.³⁶

Inspiratory Time Prolongations

A positive-pressure breath produces a flow magnitude and a flow profile that, as noted previously, can affect ventilation distribution (and thus \dot{V}/\dot{Q}). Prolonging inspiratory time, generally by adding a pause, often in conjunction with a rapid decelerating flow (i.e., pressure-targeted breath), has several physiologic effects. First, the longer inflation period may recruit more alveoli.^{38,39} Second, increased gas mixing time may improve \dot{V}/\dot{Q} matching in parenchymal lung injury (*pendelufft*).³⁸ Third, the development of PEEPi from consequently shorter expiratory times can have effects similar to those of applied PEEP (see earlier).³⁹ It should be noted, however, that the distribution of PEEPi, which is most pronounced in lung units with long expiratory time constants, may be different from that of applied PEEP and thus the effects on \dot{V}/\dot{Q} may also be different with intrinsic compared with applied PEEP. Fourth, because these long inspiratory times significantly increase total intrathoracic pressures, cardiac output may be reduced (see “[Positive-Pressure Ventilation and Cardiac Function](#)” later). And finally, inspiratory-to-expiratory ratios that exceed 1:1 (so-called inverse-ratio ventilation) are uncomfortable, and patient sedation/paralysis is often required unless a relief mechanism allows spontaneous breathing during the inflation period (see “[Airway Pressure Release Ventilation](#)” later).

Positive End-Expiratory Pressure

PEEP is defined as an elevated airway pressure at the end of expiration.³² As noted earlier, PEEP can be produced by either expiratory circuit valves (applied PEEP) or inadequate expiratory times in lung units with long expiratory time constants (PEEPi).^{21,22,38} Note that expiratory muscle contraction can also raise intrathoracic pressures at end-expiration, but this does not have the same effects on the lungs because transpulmonary pressure is not increased.

PEEP helps to recruit or maintain alveolar units open, providing several potential benefits. First, recruited alveoli improve \dot{V}/\dot{Q} matching and gas exchange throughout the ventilatory cycle.³² Second, as discussed in more detail later, patent alveoli throughout the ventilatory cycle are not exposed to the risk of injury from the shear stress of repeated opening and closing.^{40,41} Third, open alveoli with intact surfactant monolayers improve lung compliance.⁴² This is the rationale behind applying PEEP after an RM: recruited alveoli are on the deflation limb of the pressure-volume relationship and thus the pressure required to maintain

recruitment is lower than that required for initial recruitment.

PEEP, however, can also be detrimental. Because the tidal breath is delivered on top of the baseline PEEP, end-inspiratory pressures are usually raised by the application of PEEP (although this increase may be less than the actual added PEEP because of improved compliance). This increase must be considered if the lung is at risk for regional overdistention (see “[Ventilator-Induced Lung Injury](#)” later). Moreover, since parenchymal lung injury is often quite heterogeneous, appropriate PEEP in one region may be suboptimal in another and excessive in yet another.^{35,43,44} Optimizing PEEP is thus a balance between recruiting the recruitable alveoli in diseased regions without overdistending already recruited alveoli in healthier regions. Another potential detrimental effect of PEEP is that it raises mean intrathoracic pressure, thereby compromising cardiac filling in susceptible patients (see “[Positive-Pressure Ventilation and Cardiac Function](#)” section later).

MECHANICAL LOADS

Mechanical loads describe the physical requirements of ventilation with a single value, either the *pressure-time product* (PTP—the integral of pressure over time) or *work* (W—the integral of pressure over volume).^{21,22} Because mechanical loads correlate with inspiratory muscle oxygen demands,^{45-47a} the concept of load is useful in considering inspiratory muscle energy requirements during spontaneous or interactive ventilatory support. Moreover, as described in more detail later, load referenced to muscle strength and/or endurance properties (e.g., PTP or W divided by muscle pressure-generating capability) can be used to set levels of partial ventilatory support or predict spontaneous breathing capabilities.⁴⁷

Compliance, resistance, flow, and volume all contribute to the magnitude of the load per breath. During spontaneous breaths, P_{cir} is zero and integrating P_{es} over time or volume (referenced to the passive inflation pressure) describes the load borne by the inspiratory muscles to inflate the lungs. During a controlled breath, integrating P_{cir} over time or volume describes the load borne by the ventilator to inflate the entire respiratory system (lungs and chest wall) and integrating P_{es} over time or volume describes the loads imposed by the chest wall only. During interactive breaths the load is shared between patient and ventilator.⁴⁸

Under heavy loading conditions (e.g., the patient with abnormal respiratory system mechanics and thus high pressure requirements), the duration of pressure (i.e., the PTP) correlates better with muscle energetics and fatigue potential than does the volume moved with pressure (i.e., work).^{45,46} Indeed, during ventilation requiring high pressures, multiplying PTP by the inspiratory time fraction and referencing this to the maximal pressure that the inspiratory muscles can generate results in the *pressure-time index* (PTI). Muscle fatigue can be expected if the PTI value exceeds 0.15.^{48,49} The concern with high pressure loads in patients receiving partial ventilatory support is one of the rationales for providing ventilator pressure assistance with every spontaneous effort (i.e., pressure-assisted or supported breaths), as opposed to supporting only some breaths

as in intermittent mandatory ventilation without pressure support (see “[Patient-Ventilator Interactions](#)” later).⁵⁰

Inspiratory muscle overload is one of the major determinants of continuing ventilator dependency and can result either from excessive mechanical loads or from inspiratory muscle dysfunction. Excessive mechanical loads can result from disease or from inappropriate ventilatory assistance (see “[Patient-Ventilator Interactions](#)” later). Clinically, inspiratory muscle overload is manifested by rapid, shallow breathing patterns, paradoxical abdominal motion, and patient distress. Inspiratory muscle dysfunction can be a result of the systemic inflammatory response syndrome, metabolic disturbances, drugs (e.g., steroids, previous use of neuromuscular blockers), malnutrition, or malpositioning (i.e., diaphragm flattening from lung overinflation).⁵¹ Finally, insufficient loading may also affect inspiratory muscles. Specifically, controlled mechanical ventilation without any patient effort, perhaps for as little as 24 hours, may produce muscle changes similar to disuse atrophy—a condition described as *ventilator-induced diaphragmatic dysfunction* (VIDD).⁵²⁻⁵⁴

PATIENT-VENTILATOR INTERACTIONS

Mechanical ventilation modes that permit spontaneous ventilatory activity are termed “interactive” modes. These interactions can range from simple triggering of mechanical breaths to more complex processes affecting delivered flow patterns and breath timing. Interactive modes allow for muscle “exercise,” which, when performed at nonfatiguing or physiologic levels, may prevent VIDD and facilitate fatigue recovery.^{11,52-54} In addition, permitting spontaneous patient ventilatory activity with “comfortable” interactive modes may reduce the need for the sedation and/or neuromuscular blockers that may otherwise be used to prevent patients from “fighting the ventilator.”^{11,55} Interactions take place during all three phases of breath delivery: breath triggering, flow delivery, and breath cycling and are described in detail later in “Patient-Ventilator Dys-synchrony.”

POSITIVE-PRESSURE VENTILATION AND CARDIAC FUNCTION

In addition to affecting ventilation and ventilation distribution, positive-pressure ventilation can also affect cardiovascular function.⁵⁶⁻⁵⁸ In general, as mean intrathoracic pressure increases, right ventricular filling decreases and cardiac output/pulmonary perfusion consequently decreases. This is the rationale for using volume repletion to maintain cardiac output in the setting of high intrathoracic pressure. Of note, the effect of reduced cardiac filling on cardiac output may be partially counteracted by improvement in left ventricular function due to elevated intrathoracic pressure, which can reduce left ventricular afterload.⁵⁹ Importantly, in patients with left heart failure, the reduced cardiac filling and reduced left ventricular afterload effects of elevated intrathoracic pressure may improve cardiac function to the point that the removal of intrathoracic pressure may worsen cardiac function and thereby produce weaning failure.⁶⁰

Intrathoracic pressures can also influence distribution of perfusion. The relationship of alveolar pressures to perfu-

sion pressures in the three-zone West lung model helps explain this.⁶¹ Specifically, the dependent lung is generally in a zone 3 (capillary distention) state. As intra-alveolar pressures rise, however, zone 2 and zone 1 (capillary collapse/dead space) regions can appear, creating high \dot{V}/\dot{Q} units. Indeed, increases in dead space can be a consequence of ventilatory strategies employing high ventilatory pressures, as well as with those producing PEEPi.

Positive-pressure mechanical ventilation can affect other aspects of cardiovascular function. Specifically, dyspnea, anxiety, and discomfort from inadequate ventilatory support can lead to stress-related catecholamine release with subsequent increases in myocardial oxygen demands and risk of dysrhythmias.⁶⁰ In addition, coronary blood vessel oxygen delivery can be compromised by inadequate gas exchange from the lung injury coupled with low mixed venous PO_2 due to high oxygen consumption demands by the inspiratory muscles.

COMPLICATIONS OF POSITIVE-PRESSURE MECHANICAL VENTILATION

VENTILATOR-INDUCED LUNG INJURY

The lung can be injured when it is stretched excessively. The most obvious injury is barotrauma: alveolar rupture presenting as extra-alveolar air in the mediastinum (pneumomediastinum), pericardium (pneumopericardium), subcutaneous tissue (subcutaneous emphysema), pleural space (pneumothorax), or vasculature (air emboli).⁶² The risk for extra-alveolar air increases as a function of the magnitude and duration of alveolar overdistention. Thus interactions of respiratory system mechanics and mechanical ventilation strategies (high regional VT and PEEP—both applied and intrinsic) that produce regions of excessive alveolar stretch create alveolar units at risk for rupture.

Even without producing extra-alveolar air and rupture, mechanical ventilation can induce *ventilator-induced lung injury* (VILI).^{62a,62b} In experimental animals, acute lung injury can be produced by mechanical ventilation strategies that stretch the lungs beyond the normal maximum volume (at transpulmonary distending pressures of 30 to 35 cm H₂O).⁶³⁻⁶⁵ In engineering parlance, this is termed mechanical “stress.”⁶⁶ A number of clinical trials clearly indicate that ventilator strategies exposing the injured human lung to transpulmonary pressures in excess of 30 to 35 cm H₂O are associated with lung injury.⁶⁷⁻⁷⁰ Importantly, VILI may be more than simply a consequence of excessive end-inspiratory stretch. Even in the setting of transpulmonary pressures less than 30 cm H₂O, excessive tidal stretch from repetitive cycling of the lung with tidal volumes in excess of 8 to 10 mL/kg *ideal body weight* (IBW) may contribute to VILI.^{67,68} Interestingly, this VILI risk may be better quantified by referencing the tidal volume to the resting lung volume and can be termed mechanical “strain.”⁶⁶ Other ventilatory pattern factors, such as the frequency of stretch⁷¹ or the acceleration/velocity of stretch,⁷² may also be involved in the development of VILI. VILI appears to be

potentiated by a shear stress phenomenon that takes place when injured alveoli repetitively open and collapse during the ventilatory cycle (i.e., cyclical atelectasis).^{40,73,74} Vascular pressure elevations may also contribute to VILI.⁷⁵

VILI likely develops regionally when low-resistance/high-compliance units receive a disproportionately high regional tidal volume in the setting of high alveolar distending pressures (see Fig. 101-2). This can be appreciated using computed tomography under circumstances when pressures required for recruitment of diseased atelectatic regions simultaneously produce overdistention in already open, less-diseased regions (Fig. 101-3).⁷⁶ Regional protection of these healthier lung units is the rationale for using “lung-protective” ventilator strategies that accept less than normal values for pH and arterial PCO_2 in exchange for lower (and safer) distending pressures (see “Applying Mechanical Ventilatory Support” later).⁷⁷ Interestingly, data suggest that a permissive respiratory acidosis might also have therapeutic effects on alveolar injury from VILI, although the clinical applicability of this observation is not clear.⁷⁸

VILI is manifest pathologically as diffuse alveolar damage.^{40,63,64,79} Moreover, VILI is associated with cytokine release^{79,80} and bacterial translocation,⁸¹ which are implicated in the systemic inflammatory response with multorgan dysfunction that results in VILI-associated mortality.

OXYGEN TOXICITY

Very high inspired oxygen concentrations can cause oxidant injury in airways and lung parenchyma.⁸² Much of the data supporting this concept, however, has come from animals that often have quite different tolerances to oxygen than humans. It is thus not clear what the “safe” oxygen concentration or duration of exposure is in sick humans. Most consensus groups have argued that FiO_2 values less than 0.4 are safe for prolonged periods of time and that FiO_2 values of greater than 0.70 should be avoided if possible. Interestingly, several observational trials suggest that even with a “safe” FiO_2 less than 0.4, maintaining an arterial PO_2 greater than 120 to 130 mm Hg may produce systemic oxygen toxicity over time.^{83,84}

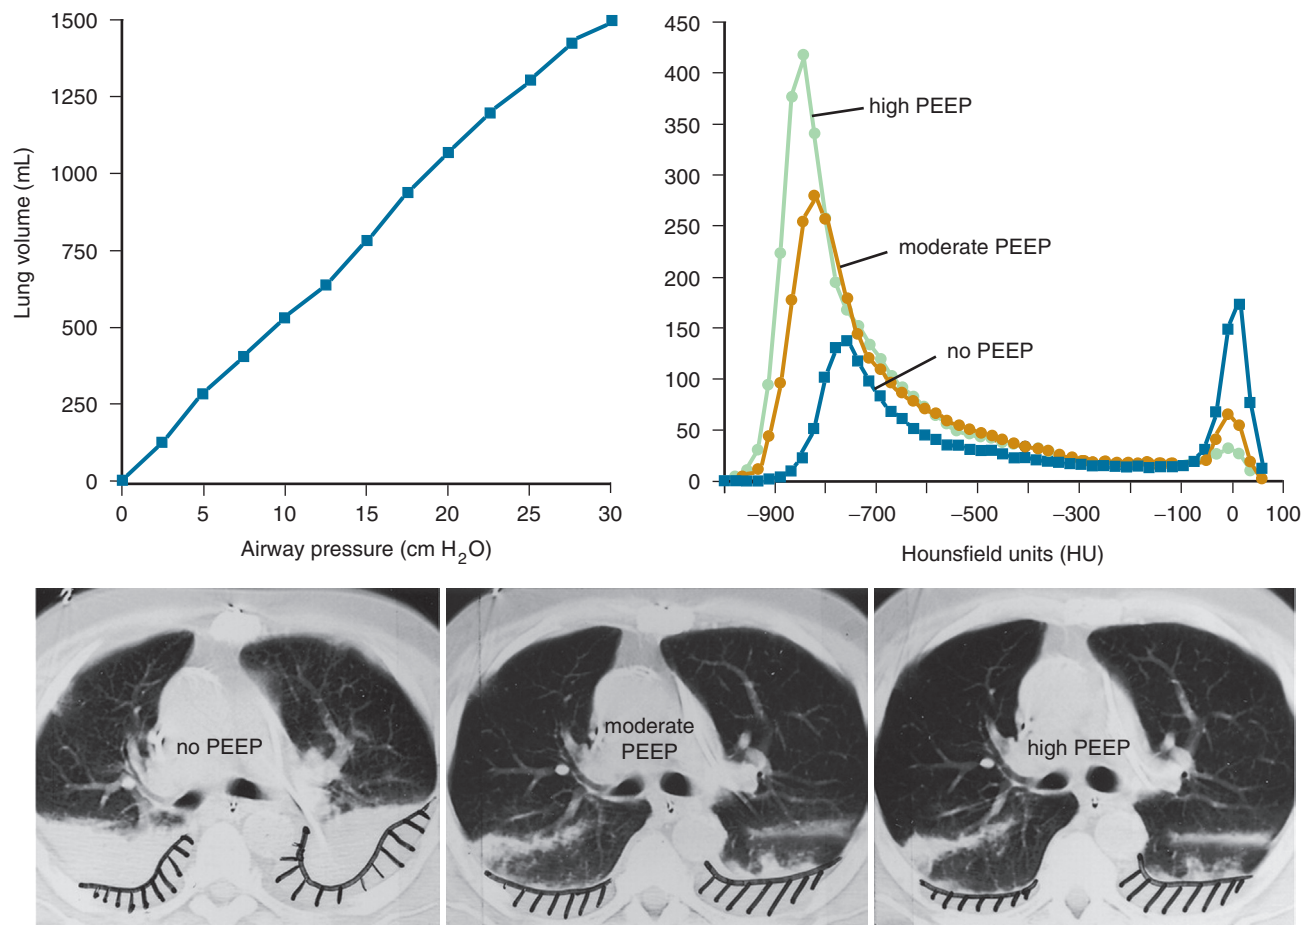

Figure 101-3 Effects of positive airway pressure in a lung with heterogeneous injury. The upper left panel shows the almost linear pressure-volume relationships as positive airway pressure is applied to the lungs. At the bottom are three representative CT lung slices at low, midrange, and maximal airway pressure. In the lung at low airway pressure (no PEEP, lower left), note the substantial atelectasis in the dependent lung regions, which is progressively reduced as airway pressure is increased (moderate PEEP and high PEEP, in the right two images). The upper right panel depicts the distribution of Hounsfield units (HUs) in each of these three CT slices, at low pressure (dark blue), at midrange airway pressure (brown), and at the highest airway pressure (light green). Note that, although increasing pressure progressively reduces the number of atelectatic units (those with CT numbers near zero), these same pressures simultaneously increase the number of overdistended lung units elsewhere in the lungs (those with CT numbers < -900 HU). (From Vieira SR, Puybasset L, Lu Q, et al: A scanographic assessment of pulmonary morphology in acute lung injury. *Am J Resp Crit Care Med* 159:1612–1623, 1999.)

PATIENT-VENTILATOR INTERFACE COMPLICATIONS

The patient must be connected to the ventilator via ventilator circuitry and an artificial airway. Problems with this interface can lead to complications. The most obvious issue is disconnection from the ventilator (including artificial airway dislodgment). Disconnections have been reported in up to 8% to 13% of ventilated patients⁸⁵ and, if left uncorrected, can be fatal. Because circuit pressure and flow can be maintained despite the disconnection of the ventilator from the patient (e.g., if the airway is in the esophagus or if the disconnected circuit remains partially occluded), it is critical that carefully set, redundant (i.e., pressure, flow, and even exhaled carbon dioxide) alarms are present.⁶ Other complications of the patient-ventilator interface include obstructions from secretions, circuit leaks, airway injury from inadequate heat/humidity, tracheal injury from the artificial airway, and loss of delivered tidal volume in a compliant circuit.

PATIENT-VENTILATOR DYS-SYNCHRONY

Patient-ventilator dys-synchrony describes the delivery of a breath from a mechanical ventilator that is not matched to patient effort. As noted earlier, this can take place during the triggering process, flow delivery, and breath cycling.

Ventilator Breath Triggering

Ventilators may sense a spontaneous effort by either an airway pressure drop or an airway flow change.^{9,10,86} Even with modern sensors, there is unavoidable dys-synchrony in the triggering process. First, a certain level of sensor insensitivity must be incorporated to avoid artifacts triggering the ventilator (i.e., “auto-triggering” due to cardiogenic oscillations). Second, even when the patient effort has been sensed, there is an inherent delay (up to 100 msec or more) in activating a valving system to open and achieve target airway flow (system responsiveness). Both of these factors can result in significant “isometric-like” pressure loads on the inspiratory muscles during the triggering process. In addition, in the setting of air trapping and PEEP_i, the elevated end-expiratory alveolar pressure acts as a triggering threshold load on the inspiratory muscles. Under these conditions, judicious use of applied PEEP can equilibrate expiratory pressure throughout the lungs and the ventilator circuit to reduce this triggering load.^{87,88}

Excessive triggering can also result from auto-triggering as noted earlier or from the triggering of a second breath when the mechanical breath cycles before the termination of patient effort (“breath stacking”). A recently described phenomenon, “entrainment,” can also result in a double breath.⁸⁹ Entrainment can be seen during a machine-triggered breath when the delivered gas flow elicits an effort. Sometimes this simply extends the breath, but if the effort persists beyond machine breath termination, a second breath can be triggered.

Ventilator-Delivered Flow Pattern

During an interactive breath, inspiratory muscles are contracting^{90,91} and the ventilator flow delivery should be adequate to provide proper muscle unloading. This does not

mean that muscle loads are eliminated. Instead, it means that a delivered flow pattern is associated with a muscle loading pattern that resembles normal, comfortable breathing¹¹ (“synchronous” flow delivery).

In general, flow synchrony is best assessed by clinical assessment and analyzing the graphic representation of circuit pressure over time.^{11,92} Flow synchrony is manifest clinically as a relaxed patient who does not appear dyspneic. In contrast, flow dys-synchrony is often manifest as tachypnea, air hunger (dyspnea), and the appearance of “flow starvation.”¹¹ With synchronous flow delivery, the circuit pressure graph should maintain either a steady baseline profile (a CPAP breath) or a convex upward shape (assisted/supported breath) indicating that flow is proportional to demand. Dys-synchrony (and imposed loading) is said to exist when the circuit pressure graph is literally “sucked downward” by effort in excess of flow delivery, often below the baseline^{11,93} (Fig. 101-4).

Breath Cycling

Cycling dys-synchrony can arise in one of two ways. First, if the mechanical breath lasts beyond the duration of patient effort, an inadequate expiratory time may develop (along with air trapping) and/or patient expiratory efforts may be required to terminate the breath.¹¹ This can be a particular concern when using PS breaths in obstructive airway disease—the relatively steady inspiratory flow with PS in these patients coupled with the PS flow-cycling algorithm may significantly delay breath termination.⁹⁴ Second, if the mechanical breath terminates before the patient effort is finished, the patient may be left demanding additional flow without any being delivered. Significant imposed

Figure 101-4 Flow and pressure pattern differences during dys-synchronous and synchronous breaths in a patient with a vigorous inspiratory effort. Depicted are flow (upper panel), volume (middle panel), and pressure (lower panel) for a dys-synchronous flow-targeted breath (left) and a more synchronous pressure-targeted breath (right) with matched mean flow, inspiratory time, and tidal volume. Note that, during the flow-targeted breaths (left), the fixed flow does not respond to the vigorous inspiratory effort, resulting in the circuit pressure being “sucked” downward (solid arrow). In contrast, with the pressure-targeted breath, flow adjusts and increases to meet the inspiratory effort better (dashed arrow). (Redrawn from Yang LY, Huang YC, MacIntyre NR: Patient-ventilator synchrony during pressure-targeted versus flow-targeted small tidal volume assisted ventilation. *J Crit Care* 22:252–257, 2007.)

loading and, as noted earlier, double breath triggering may result.¹¹

Clinical Implications

Determining the prevalence of patient-ventilatory dys-synchrony is difficult because studies examining this question have used heterogeneous patient populations and different definitions of dys-synchrony, methods of detection, duration and timing of observation, and ventilatory modes.^{11,95} Triggering dys-synchronies have been the most well studied. Depending on patient population, ventilator settings, and measurement techniques, triggering dys-synchronies have been reported in 26% to 82% of mechanically ventilated patients. Not surprisingly, trigger dys-synchronies were more common in patients with COPD and those at risk for intrinsic PEEP development.^{11,95} Double triggering is the other commonly reported triggering dys-synchrony but is generally described in less than 10% of patients in these various studies.^{11,95}

The incidence of other forms of dys-synchrony (flow dys-synchrony and cycle dys-synchrony) has not been as well characterized. However, a retrospective evaluation of the National Institutes of Health ARDS Network small tidal volume study reported cycling dys-synchronies associated with double triggering in 9.7% of all breaths analyzed.⁹⁶ Indeed, it is likely that patient-ventilatory dys-synchrony is ubiquitous if any patient is observed long enough during assisted/supported mechanical ventilation, especially if more sophisticated monitors (e.g., Pes or diaphragmatic electromyograms) are employed to detect patient effort.

Although there is no doubt that many dys-synchronies are subtle and of little clinical relevance, significant dys-synchronies may be missed, thus overloading respiratory muscles and producing patient discomfort, which is a frequently cited indication for the administration of sedatives.^{11,95} This may impact ventilator duration because high sedation usage is linked to longer ventilator use. Indeed, several observational studies have noted more days of mechanical ventilation and even trends toward higher mortality in patients with trigger dys-synchronies taking place more than 10% of the time.⁹⁵

Managing Dys-synchronies

Synchronous ventilator settings first require setting the trigger to as sensitive a setting as possible (without auto-triggering). If PEEP_i is creating a triggering load, attempts should be made to minimize PEEP_i and then judicious use of applied PEEP added to counterbalance the imposed triggering load as described later. If entrainment is present, reducing sedation and the need for a mandatory (controlled) breath rate should be re-assessed.

Flow synchrony is often easier to achieve with variable flow pressure-targeted breaths, as noted earlier. Pressure-targeted breaths can also allow for adjustments in the rate of pressure rise and can compensate for endotracheal tube resistance, as means of further enhancing synchrony (see “Recent Innovations in Mechanical Ventilatory Support” later). If flow-targeted breaths are desired, synchrony can be addressed with adjustments in flow magnitude and profile (sine wave, square wave, decelerating pattern). Importantly, because the patient’s respiratory drive is modulated by mechanical feedback from the lungs and thorax,

modes that avoid multiple different breath types (i.e., avoiding SIMV) tend to facilitate flow synchrony.¹¹ Finally, breath duration should be optimized for comfort and for elimination of double breaths by using adjustments in the cycle variable (volume, time, or flow).

Two new modes (*proportional assist ventilation* [PAV] and *neurally adjusted ventilatory assistance* [NAVA]) have been used over the past decade to enhance synchrony further. These are described in more detail later in “Recent Innovations in Mechanical Ventilatory Support.”

PULMONARY INFECTIOUS COMPLICATIONS

Mechanically ventilated patients are at risk for pulmonary infections for several reasons.⁹⁷ First, the natural glottic closure protective mechanism is compromised by an endotracheal tube. This permits continuous seepage of oropharyngeal material into the airways. Second, the endotracheal tube itself impairs the cough reflex and serves as an additional potential portal for pathogens to enter the lungs. This is particularly important if the circuit is contaminated. Third, airway and parenchymal injury both from the underlying disease and from management complications make the lung prone to infections. Fourth, the ICU environment itself, with its heavy antibiotic use and presence of sick patients in close proximity, increases risk for a variety of infections.

Preventing *ventilator-associated pneumonia* (VAP) is critically important because the development of VAP heavily influences both length of stay and mortality.⁹⁷⁻¹⁰⁰ Care “bundles” linked to better outcomes include handwashing, elevating the head of the bed, oral care with chlorhexidine, and carefully chosen antibiotic regimens for other infections. Management strategies that avoid breaking the integrity of the circuit (e.g., by changing the circuit only when visibly contaminated) also appear to be helpful.^{98,99} Continuous drainage of subglottic secretions may be another simple way of reducing lung contamination by oropharyngeal material.^{98,99} More controversial are devices to cleanse the endotracheal tube or make it resistant to biofilm buildup.¹⁰¹

Another concept explored in small trials is the use of aerosolized antibiotics in patients with purulent secretions to reduce progression of tracheobronchitis to ventilator-associated pneumonia.¹⁰² Finally, prompt discontinuation of ventilatory support when clinically appropriate will help minimize the time patients are exposed to infection risks.

APPLYING MECHANICAL VENTILATORY SUPPORT

MECHANICAL VENTILATORY SUPPORT INVOLVES TRADEOFFS

The goals of providing adequate support while minimizing the risk of VILI and other complications involves tradeoffs. Specifically, the need for potentially injurious pressures, volumes, and supplemental O₂ must be weighed against the benefits of supporting gas exchange. To this end, a “re-thinking” of gas exchange goals has taken place over

the past 2 decades so that now, pH levels as low as 7.15 to 7.20 and Po_2 values as low as 55 mm Hg are often considered acceptable in order to protect the lung.^{70,78,103} Ventilator settings are thus selected to provide at least this level of gas-exchange support while meeting three mechanical goals: (1) provision of enough PEEP to recruit the “recruitable” alveoli, (2) avoidance of a PEEP-tidal volume combination that unnecessarily overdistends lung regions at end-inspiration, and (3) limiting tidal volumes to the physiologic range. These goals embody the concept of a lung-protective mechanical ventilatory strategy. Currently, these principles guide recommendations for the specific management of various forms of respiratory failure.¹⁰⁴⁻¹⁰⁷

CONSIDERATIONS IN CHOOSING VENTILATOR SETTINGS FOR DIFFERENT FORMS OF RESPIRATORY FAILURE

Parenchymal Lung Injury

Parenchymal lung injury means injury that involves the air spaces and the interstitium of the lung.³¹⁻³⁵ In general, parenchymal injury stiffens lungs and decreases lung volumes. It is important to realize that there are often marked regional differences in the degree of mechanical abnormalities, which interact with the particular ventilatory strategy. This is because delivered gas will preferentially go to the more normal regions, those with higher compliance and lower resistance, rather than to abnormal regions (see Fig. 101-2). A “normal-sized” tidal volume may thus be distributed preferentially to the healthier regions, resulting in a regional overdistention injury. Parenchymal injury can also affect the airways, especially the bronchioles and alveolar ducts. These narrowed and collapsible small airways can also reduce regional ventilation to injured lung units, leading to regions of air trapping and possibly cyst formation during the healing phase.

Gas-exchange abnormalities in parenchymal lung injury are a consequence of alveolar consolidation, flooding, and/or collapse producing a maldistribution of ventilation and resulting in \dot{V}/\dot{Q} mismatching and shunts.³¹⁻³⁵ Because \dot{V}/\dot{Q} mismatching and shunt are more of an issue than dead space in parenchymal lung disease, hypoxemia tends to be more of a clinical problem than carbon dioxide elevation.

Frequency-tidal volume settings for patients with parenchymal lung injury must focus on limiting end-inspiratory stretch. The benefit of reducing stretch in improving outcome has been suggested by several clinical trials^{67-70,108} but has been most convincingly demonstrated by the National Institutes of Health (NIH)-sponsored ARDS Network Trial in which a ventilator strategy using a V_T of 6 mL/kg predicted body weight (PBW) as compared with 12 mL/kg PBW led to a 10% absolute reduction in mortality.⁷⁰ Thus initial V_T settings should start at 6 mL/kg PBW.^{68,109} Moreover, strong consideration should be given to reducing this setting further if end-inspiratory Pplat exceeds 30 cm H_2O .⁶⁷⁻⁷⁰ Increases in the V_T settings might be considered if there is marked patient discomfort or suboptimal gas exchange provided that the subsequent Pplat values do not exceed 30 cm H_2O .⁶⁷⁻⁷⁰ Respiratory rate settings are then adjusted to control pH. Unlike the case in obstructive

diseases, the potential for air trapping in parenchymal lung injury is low if the breathing frequency is less than 35 breaths/min; air trapping may not develop even at frequencies exceeding 50 breaths/min.

There is controversy as to whether *neuromuscular blockade* (NMB) and totally machine-controlled mechanical ventilation should be used in the initial 24 to 48 hours of parenchymal lung injury. NMB use producing flaccid ventilatory muscles reduces total body oxygen demands and eliminates potential dys-synchronous interactions. Indeed, one study in patients with severe hypoxemia (arterial Po_2/Fio_2 ratios < 120) showed improved mortality with NMB use for 48 hours.¹¹⁰ However, as noted earlier, ventilatory muscles inactive for as little as 24 hours are at risk for VIDD and long-term disability.⁵²⁻⁵⁴ Moreover, the use of NMB usually requires substantial sedative use. As a consequence, many authorities would argue that assisted/supported breaths are preferable early in the course of mechanical ventilatory support. The inspiratory time and the I:E ratio in parenchymal injury is set with consideration of several issues. The usual initial I:E ratio setting is 1:2 to 1:4, the normal and the most comfortable setting. The flow graphic should also be assessed to ensure that cycle synchrony is present and the expiratory time is adequate to avoid air trapping. An I:E ratio greater than 1:1 is referred to as *inverse-ratio ventilation* (IRV). In severe respiratory failure, IRV can be employed as an alternative to increasing PEEP to improve \dot{V}/\dot{Q} matching.^{38,39} The beneficial mechanisms involved include longer mixing times, recruitment of slowly filling alveoli, and development of PEEPi. A variation on IRV is *airway pressure release ventilation* (APRV).¹¹¹⁻¹¹⁵ APRV incorporates the ability to breathe spontaneously during the long inflation period of a pressure-controlled breath—a feature that may enhance recruitment and gas mixing. APRV is discussed in more detail in “Recent Innovations in Mechanical Ventilation” later.

The PEEP/ Fio_2 settings are optimized using both mechanical and gas-exchange considerations. Conceptually, in setting the PEEP level in parenchymal lung injury, the goal is to provide ventilator settings between the upper and lower inflection points on the deflation limb of the pressure-volume curve.¹¹⁶ The most direct mechanical approaches use the static pressure-volume plot to set the PEEP and V_T . This traditionally involves multiple $\text{V}_\text{T}/\text{Pplat}$ measurements and requires considerable clinician time along with patient sedation or even neuromuscular blockade and is not widely used. Another mechanical approach uses step changes in PEEP to determine the PEEP level that gives the best compliance.¹¹⁷ A simpler mechanical approach analyzes the $\text{P}_{\text{c}}\text{ir}$ profile during a constant-flow breath (stress index) to detect overdistention (late rising profile) or collapse/reopening injury (early rising profile).¹¹⁸ With all of these approaches, a recruitment maneuver can be used to recruit the maximal number of recruitable alveoli before setting the PEEP. Fio_2 adjustments are then set as low as clinically acceptable.

PEEP can also be guided by gas-exchange criteria, usually involving algorithms that adjust PEEP and Fio_2 according to certain targets. Note that constructing a PEEP/ Fio_2 algorithm is usually an empirical exercise in balancing distending pressure, arterial O_2 saturation, and Fio_2 and depends on the clinician’s perception of the relative “toxicities” of high thoracic pressures, high Fio_2 , and low arterial

Figure 101-5 Two positive end-expiratory pressure (PEEP)/F_{IO}₂ algorithms that have been used in National Institutes of Health Acute Respiratory Distress Syndrome Network clinical trials. Plotted are F_{IO}₂ on the horizontal axis and PEEP on the vertical axis. With both approaches, the oxygenation target (PaO₂ 55 to 80 mm Hg, SPO₂ 88% to 95%) and the maximal allowable plateau pressure (35 cm H₂O) is the same. Patients are moved in steps up and down the algorithm according to these targets. The two algorithms depicted either focus on higher PEEP levels (“high PEEP”—brown bars) or lower PEEP levels (“low PEEP”—blue bars). (Courtesy Art Wheeler, MD, personal communication and Ref. 70.)

O₂ saturation. Although most of the reported PEEP/F_{IO}₂ algorithms generally target modest levels of oxygenation (e.g., arterial PO₂ 55 to 80 mm Hg or SO₂ 88% to 95%), they tend to segregate into approaches that focus either on higher PEEP levels (“high PEEP” algorithms) or lower PEEP levels (“low PEEP” algorithms) (Fig. 101-5). Several trials have compared high versus low PEEP algorithms in conjunction with low tidal volume/limited Pplat strategies in patients with ARDS.¹¹⁹⁻¹²¹ A meta-analysis of trials with mild ARDS (arterial PO₂/F_{IO}₂ > 200) compared with more severe ARDS (arterial PO₂/F_{IO}₂ < 200) demonstrated that higher PEEP strategies had a significant mortality benefit in more severe ARDS, whereas low PEEP strategies showed a trend toward a potential benefit in mild ARDS.¹²²

In patients with abnormal chest wall mechanics (i.e., stiff chest walls from obesity, anasarca, abdominal compartment syndrome, and even systemic inflammation), the reliance on circuit airway pressures to guide ventilator settings will ignore the effect of elevated pleural pressures on reducing transpulmonary pressure, the ultimate determinant of VILI and alveolar recruitment. Under these circumstances, clinicians should consider modest empirical increases in applied PEEP and allowances of an increased Pplat beyond the limits described earlier. Alternatively, an esophageal catheter to measure Pes could be inserted to assess transpulmonary pressure directly and adjust settings accordingly.^{19,123} Indeed, one clinical trial using Pes to guide PEEP settings suggested improved outcomes.¹²³

Obstructive Airway Disease

Increases in airway resistance lead to respiratory failure from airflow obstruction and create two important pathophysiologic changes. First, the increased pressures required for airflow may overload inspiratory muscles, producing a “ventilatory pump failure” in which spontaneous minute ventilation becomes inadequate for gas exchange. Second, the narrowed airways create regions of lung that cannot properly empty and return to their normal “resting volume,” thereby producing PEEPi.²⁷ These regions of overinflation create dead space and put inspiratory muscles at a substan-

tial mechanical disadvantage that further worsens muscle function. Overinflated regions may also compress more healthy regions of the lung, impairing \dot{V}/\dot{Q} matching. Regions of air trapping and PEEPi also function to increase the threshold load the patient must overcome to trigger mechanical breaths, as noted earlier.

The gas-exchange abnormalities in the setting of worsening airflow obstruction are several. First, although there may be a transient hyperventilation due to dyspnea in the asthmatic patient, the worsening respiratory failure in obstructive lung disease is generally characterized by a falling minute ventilation as inspiratory muscles fatigue in the face of airflow obstruction. The result is termed *hypercapnic respiratory failure*. Second, as noted earlier, regional lung compression and regional hypoventilation produce \dot{V}/\dot{Q} mismatch that results in progressive hypoxemia. Alveolar inflammation and flooding, however, are not characteristic features of respiratory failure due to pure airflow obstruction, and thus shunts are less of an issue than in parenchymal lung injury. Third, overdistended regions of the lung coupled with underlying emphysematous changes in some patients result in capillary loss and increasing dead space. This wasted ventilation further compromises the ability of the inspiratory muscles to supply an adequate ventilation for alveolar gas exchange. These emphysematous regions also have low recoil properties, which can worsen air trapping. Fourth, hypoxemic pulmonary vasoconstriction coupled with chronic pulmonary vascular changes in some airway diseases overload the right ventricle, further decreasing blood flow to the lung and increasing dead space further.

Frequency-tidal volume settings in obstructive diseases are chosen on the basis of many considerations similar to those in parenchymal lung injury. Specifically, tidal volumes should be in the 6 to 8 mL/kg (IBW) range with Pplat targets of less than 30 cm H₂O.⁶⁷⁻⁷⁰ In obstructive diseases, however, clinicians should also be aware that high *peak* airway pressures, even in the presence of acceptable values for Pplat, may transiently subject regions of the lung to periods of overdistention injury (see Fig. 101-2). Finally, setting the VT should also take into consideration the potential to develop PEEPi with its consequent impact on Pplat elevations and the risk of overdistention injury.

The ventilatory rate is used to control pH. Unlike the situation in parenchymal disease, however, the elevated airway resistance (and often the low recoil pressures of emphysema) greatly increase the potential for PEEPi and thus limit the range of breath rates available. Indeed, reductions in both VT and ventilatory rate to levels resulting in hypoventilation and “permissive (or even “therapeutic”⁷⁸) hypercapnia” may be an appropriate tradeoff to limit PEEPi development and overdistention.

The I:E ratio in obstructive lung disease is generally set as low as possible to minimize the development of air trapping. For the same reason, approaches using IRV strategies are almost always contraindicated.

The PEEP/F_{IO}₂ settings assume a different role in obstructive lung disease than in parenchymal lung disease. Because alveolar recruitment is less of an issue and overdistention is more of an issue in obstructive lung injury than in parenchymal lung injury, the strategy in using the PEEP/F_{IO}₂

steps in Figure 101-5 should probably be shifted more toward the use of FiO_2 for oxygenation support instead of PEEP. A specific role for PEEP in the obstructed patient arises when PEEPi serves as an added inspiratory threshold load on the patient attempting to trigger a breath, as described earlier. Under these conditions, judicious application of circuit PEEP (at levels up to 75% to 85% of PEEPi) can “counterbalance” PEEPi throughout the ventilator circuitry to reduce this triggering load and facilitate the triggering process.^{87,88}

In severe airflow obstruction, the use of the low-density gas helium can help facilitate ventilation. Helium mixtures are available as 80:20, 70:30, or 60:40 helium:oxygen breathing gas mixtures (heliox) and can both reduce patient inspiratory work and facilitate lung emptying (recall that driving pressure decreases and/or flow increases as gas density decreases).¹²⁴ However, to date there have been no studies demonstrating improved outcomes with the use of heliox. With a helium:oxygen gas mixture, it should be remembered that many flow sensors must be recalibrated to account for the change in gas density.

Finally, it is important to note that noninvasive ventilation has been demonstrated most convincingly to improve outcomes in patients with obstructive diseases.¹²⁵ In setting up noninvasive ventilation, the same principles described previously for invasive mechanical ventilation also apply (see Chapter 102).

Neuromuscular Respiratory Failure

The risk of VILI is generally less in a patient with neuromuscular failure (e.g., central nervous system injury, drug overdoses, anesthesia) because lung mechanics are often near normal and regional overdistention less likely. More “generous” VTs (e.g., up to 10 mL/kg PBW) have thus been proposed as being useful to improve comfort, maintain recruitment, prevent atelectasis, and avoid hypercarbia that may adversely affect central nervous system function. However, this notion has been challenged recently by clinical trials of patients with normal lungs in the perioperative period showing reduced postoperative complications when VTs are used in the 6 to 8 mL/kg (IBW) range. Regardless of VT settings, maximal distending pressures should be kept as low as possible while still being compatible with the other goals noted previously.⁶⁷⁻⁷⁰

Mode selection in neuromuscular disease patients is often determined by patient comfort and reliability of the respiratory drive. PEEP, even at low levels, is often beneficial at preventing derecruitment (atelectasis) in these patients, who are often supine and unable to clear secretions or sigh.

Recovering Respiratory Failure—“Weaning” and Discontinuation Process

As respiratory failure stabilizes and begins to reverse, clinical attention shifts to the process of ventilator withdrawal. Unfortunately, a number of large clinical trials have clearly demonstrated that current assessment/management strategies are not optimal, resulting in considerable delay in ventilator withdrawal.^{125,126} Such delay leads to increased length of ICU stay, increased costs, prolonged exposure to circuit pressure, and increased risk of infection. Attempts to speed withdrawal, however, must be balanced against the

risk of premature withdrawal with consequent loss of airway patency, aspiration, and inspiratory muscle fatigue. An evidence-based task force¹²⁵ has recommended a two-step process:

1. Consider a patient a candidate for withdrawal if (a) the lung injury is stable/resolving, (b) the gas exchange is adequate with low PEEP/ FiO_2 requirements, (c) the hemodynamics are stable without pressors, and (d) the patient has the capability to initiate spontaneous breaths.
2. In these patients, perform a spontaneous breathing trial (using T-piece, CPAP, or pressure support at 5 cm H_2O) for 30 to 120 minutes. Assessments should include the ventilatory pattern, gas exchange, hemodynamics, and comfort. Patients “passing” this trial should be considered for ventilator withdrawal.

In patients passing the *spontaneous breathing trial* (SBT), separate assessments are required to determine if the artificial airway can be removed. These involve cough strength, suctioning frequency, and, to a certain extent, the ability to follow commands.¹²⁵ Cuff leak, a bedside test that may demonstrate whether there is airway edema or compression around the endotracheal tube that could lead to postextubation airway obstruction, does not appear to be an important predictor of success, except perhaps in the setting of prior upper airway injury. Extubation failures can be expected in 10% to 20% of all extubations. Many of these involve airway protection issues and thus indicate the need for prompt reintubation. However, in some patients, especially those with chronic obstructive pulmonary disease, an extubation failure caused by increasing inspiratory muscle overload might be managed by noninvasive ventilation.^{127,128}

In patients failing the SBT, a stable and comfortable level of support should be provided until the next SBT.¹²⁵ Frequent (e.g., every 2 to 12 hours) support reductions are usually not necessary because they have not been shown to speed up the withdrawal process and only serve to consume resources and expose the patient to the risks of muscle overload. Repeat assessments for SBTs, however, should be done daily.^{125,126} Importantly, aggressive strategies to reduce sedation can accelerate this process.¹²⁹ Indeed, some have advocated “spontaneous awakening trials” coupled to SBTs, but it is not clear if this approach is superior to carefully targeted sedation protocols.¹³⁰

A common problem seen in patients recovering from respiratory failure but still deemed in need of an artificial airway is the presence of large VTs despite low levels of ventilatory support (e.g., inspiratory pressure levels of 5 cm H_2O). Under these circumstances, a search should be made for causes of an excessive respiratory drive such as pain, metabolic acidosis, or anxiety, and these issues should be addressed. Most would argue that, in the absence of reversible causes, sedation should not be used simply to lower the VT.

Regardless of the clinical scenario, whenever assisted-supported breaths are used, attention must be paid to assuring synchronous interactions. As noted earlier, this first means addressing the appropriateness of respiratory drive to ensure that reversible causes of excess drive (e.g., pain, anxiety, acidosis) are managed and then providing settings

that maximize trigger sensitivity. It also ensures proper flow and cycle synchrony.

RECENT INNOVATIONS IN MECHANICAL VENTILATORY SUPPORT

INNOVATIVE STRATEGIES FOR “LUNG PROTECTION”

Several innovations introduced recently may assist clinicians in reducing ventilator-induced lung injury. Among the more interesting are *airway pressure release ventilation* (APRV) and *high-frequency ventilation* (HFV). In addition, ventilating patients in the prone position, although not novel, can also be viewed as an interesting strategy to facilitate lung protective ventilation.

Airway Pressure Release Ventilation

APRV (also known as *biphasic ventilation*, *bilevel ventilation*, and *bilevel positive airway pressure*) is a time-cycled, pressure-targeted form of ventilatory support.¹¹¹⁻¹¹⁵ It is actually a modification of pressure-targeted SIMV that allows spontaneous breathing (with or without PS) during both the inflation and deflation phases.

The putative advantages of this approach are similar to others that utilize long inspiratory times. Specifically, the long inflation phase recruits more slowly filling alveoli and raises mean airway pressure without increasing applied PEEP (although PEEPi can develop with short deflation periods). Unlike older IRV strategies that required paralysis, however, the additional spontaneous efforts during inflation may enhance both recruitment and cardiac filling when compared with other controlled forms of support. Although IRV strategies are usually reserved for severe forms of respiratory failure in which airway pressures and FIO_2 levels are approaching potentially injurious levels, the comfort and recruitment potential associated with APRV may prompt consideration of its use even in less severe forms of lung injury.

Good gas exchange has been demonstrated with APRV in several small observational clinical trials, often with lower maximal airway pressures than used with control ventilation.¹¹¹ However, the end-inspiratory lung distention in APRV may not be less than that provided during other forms of support (and, indeed, it could be substantially higher) because spontaneous VTs can expand the lung beyond the volume at the APRV set pressure. In the few randomized studies that compare APRV to a true lung-protective strategy, no differences in important outcomes have been found.¹¹³⁻¹¹⁵

High-Frequency Ventilation

HFV uses high breathing frequencies (120 to 900 breaths/min in the adult) coupled with small VTs (usually < anatomic dead space and often < 1 mL/kg IBW at the alveolar level) to provide gas exchange in the lungs.¹³¹ Gas transport under these seemingly unphysiologic conditions may involve such mechanisms as Taylor dispersion, coaxial flows, and augmented diffusion.¹³²

HFV can be supplied by either jets or oscillators. Jets inject high-frequency pulses of gas into the airways. Oscillators literally vibrate a fresh bias flow of gas delivered at the tip of the endotracheal tube. Because of this, oscillatory HFV has sometimes been referred to as “CPAP with a wiggle.”

The putative advantages of HFV are twofold. First, the small alveolar tidal pressure swings minimize cyclical overdistention and derecruitment. Second, a high mean airway pressure can also prevent derecruitment. Interestingly, mean pressures used during HFV are often reported to exceed the 30 to 35 cm H_2O threshold employed during conventional ventilation. This tolerance of a higher mean pressure with HFV may be explained by a better maintained alveolar structure with a slowly applied (albeit vibrating) constant pressure as opposed to cyclical brief tidal pressures.¹³³

Clinical experience with HFV has been most extensive in the neonatal and pediatric age groups where a number of trials show improved long-term lung function when HFV is used in acute respiratory failure.^{134,135} Although adult experience with HFV is less, a meta-analysis of randomized trials using HFV in adult respiratory failure suggested an outcome benefit to HFV.¹³⁶ Two large subsequent trials, however, have called this conclusion into question. In one, mortality was identical in both the HFV and lung-protective conventional strategy¹³⁷; in the other, the trial was stopped early because of increased mortality in the HFV group.¹³⁸ Of concern in both of these trials was the use of many centers that had little or no previous experience with HFV. Nevertheless, both trials make it clear that HFV, if used, is best reserved for patients failing conventional lung protective strategies and should be employed by clinicians experienced in the use of HFV.

Positive-Pressure Ventilation in the Prone Position

Mechanical ventilation of patients in the prone position offers several physiologic advantages.¹³⁹ Chief among these are two mechanisms that can improve ventilation distribution. First, the heart no longer rests on the left lower lobe and this allows better ventilation distribution to that region. Second, the sternum is restricted in its ability to move outward. This functionally stiffens the chest wall and forces a more even distribution of positive pressure.

Prone positioning has its challenges, primarily from a nursing perspective. The act of proning requires careful teamwork (although automated proning beds exist). More importantly, management of vascular lines, feeding tubes, artificial airways, ostomies, and so on need careful attention because they can be easily dislodged. Avoiding facial pressure sores also requires careful nursing care.

There have been a number of randomized controlled trials of proning in patients with ARDS and, until recently, despite consistently better oxygenation, no consistent outcome benefit could be demonstrated.¹³⁹ However, the largest study to date focusing on ARDS patients with arterial PO_2/FIO_2 ratios less than 150 recently showed a significant mortality benefit to lung protective mechanical ventilation provided in the prone position for more than 16 hours/day.¹⁴⁰

AUTOMATED WEANING STRATEGIES

Over the years, a number of attempts have been made to “automate” the weaning process.⁷ An early example is minimum minute ventilation, which adjusted the intermittent mandatory breath rate according to the level of spontaneous ventilation. The concept behind automated weaning was that significant clinician time could be saved and ventilatory support could be automatically reduced in a timely fashion on the basis of simple ventilator measurements.

Volume support (VS, also known by trade names such as “Automatic Pressure Ventilation”) is a newer strategy with the potential for automatic support reduction.⁷ As described earlier, VS is a pressure support mode that uses tidal volume as a feedback control for continuously adjusting the pressure support level. Proponents claim that this approach could “automatically” wean a patient by reducing pressure support as patient effort increases and respiratory system mechanics improve. Conversely, pressure support would increase if patient effort diminished or respiratory system mechanics worsened. Similarly, it has also been suggested that VS may be a useful way to maintain a more constant level of partial support in patients with fluctuating levels of effort related to drugs or neurologic conditions. All of these effects have been demonstrated in small studies focused on patients with rapidly recovering respiratory failure.⁷

Unfortunately, the simplicity of VS may introduce problems.^{7,26} For instance, if the volume set by the clinician is excessive for patient demand, a recovering patient may not attempt to take over the work of breathing for that volume and thus weaning may not progress. In addition, if the pressure level increases in an attempt to maintain an inappropriately high-set V_T in the patient with airflow obstruction, PEEP_i may result. Conversely, if the volume set by the clinician is not adequate for patient demand, a patient may not receive adequate support. Under these conditions, a patient will perform excessive work to maintain a certain V_T even as the inspiratory pressure is being reduced. A transient increase in patient demand from pain or anxiety could also result in inappropriate support reduction with VS.²⁶

Adaptive support ventilation (ASV) has a sophisticated algorithm to adjust the ventilatory pattern during machine-triggered breaths as described earlier. However, ASV performs similarly to VS during patient-triggered breaths. Small clinical studies have demonstrated that ASV can automatically wean ventilatory support safely.¹⁴¹ However, large trials comparing ASV weaning to regular daily SBT strategies have not been done.

Another commercially available feedback system for weaning pressure-targeted breaths uses not only V_T but also respiratory rate and end-tidal carbon dioxide to adjust ventilator settings.¹⁴² Randomized trials with this system, however, have not shown faster ventilator withdrawal when compared with strategies using protocols for regular SBTs.¹⁴³

Inherent in all of these automated weaning systems is the notion that gradual support reductions (weaning) in between SBTs facilitates ventilator withdrawal—a notion that has little, if any, evidence supporting it in patients recovering from acute respiratory failure.¹⁴⁴ Two clinical

scenarios, however, may be amenable to these automated approaches: The first is the patient rapidly recovering from sedatives/anesthesia where these systems can alert clinicians to the return of adequate spontaneous efforts. The second is the patient requiring prolonged mechanical ventilation who has failed multiple SBTs. Under these circumstances, an automated support reduction system could serve as a diagnostic tool alerting the clinician to recovery of respiratory function and the possibility of reinstating SBTs.

OPTIMIZING SYNCHRONY DURING INTERACTIVE BREATHS

Interactive breaths are commonly used during mechanical ventilatory support to improve comfort (and reduce sedation), especially during the recovery phase of respiratory failure. As noted previously, interactive breaths need to be synchronous with patient efforts during all three phases of breath delivery: trigger, flow delivery, and cycle. A number of recent innovations have been introduced and are reviewed here.

Although all of these innovations have conceptual appeal and have been shown to perform as designed in both bench testing and small clinical observational trials, patient outcomes, including sedation needs, ventilator days, or patient comfort assessments, have generally not been studied. Nevertheless, their straightforward designs, ease of operation, and safety make these innovations appropriate to consider in patients receiving interactive breaths.

Endotracheal Tube Resistance Compensation

The endotracheal tube provides a significant resistance to flow during both inspiration and expiration. During the inspiratory phase, this means that pressure build-up in the airways “lags” behind the pressure build-up in the ventilator circuitry. Thus the “square” wave of pressure in the circuitry provided by a pressure-targeted breath is distorted in the airways to a slower rise of pressure. This may create significant initial flow dys-synchrony in patients with vigorous inspiratory efforts. During expiration, a similar gradient between airway pressures and set circuit PEEP can develop.

One way to address this is to target ventilator pressures to a measured tracheal pressure distal to the endotracheal tube. Unfortunately, readings from intra-airway pressure sensors over prolonged periods are not reliable. Another approach is to account for endotracheal tube resistance mathematically in the ventilator flow delivery pattern.^{145,146} Known by various trade names (e.g., “Automatic Airway Compensation,” “Automatic Tube Compensation”), this approach initially provides an inspiratory pressure higher than the set pressure target. As inspiration proceeds, this delivered pressure then tapers to the set inspiratory pressure target. This compensation mechanism can also operate in expiration with an initial expiratory airway pressure below the set PEEP that then rises to the set PEEP. A more square wave pattern of inspiratory and expiratory tracheal pressures is the result.^{145,146}

Applying endotracheal tube resistance compensation is relatively straightforward. Clinicians must input the characteristics of the endotracheal tube. Thereafter, the

ventilator provides the appropriate circuit pressure profile during both inspiration and expiration to create the desired square wave pattern in the trachea. Although outcome studies using this compensation approach have not been done, the conceptual appeal should make it a consideration in virtually all patients receiving assisted/supported pressure-targeted breaths—especially those with vigorous inspiratory efforts.

Pressure Rate of Rise (Slope) Adjusters

The original design for pressure-targeted breaths (pressure support and pressure assist-control) had a programmed flow delivery algorithm that attempted to reach the target inspiratory pressure quickly, without causing an uncomfortable overshoot. Newer ventilators, however, allow the clinicians to adjust the rate of rise of this pressure (slope adjusters), and clinical studies have suggested that slope adjustment could significantly enhance flow synchrony in many patients.¹⁴⁷ Specifically, these studies found that a rapid rate of rise was often desired in a patient with vigorous flow demands, whereas a much slower rate of rise was often preferable in patients with less vigorous demands.

There are several approaches to setting the slope adjuster. The most direct way is to use the circuit pressure graph and adjust the slope to create a “smooth square wave” appearance to the circuit pressure profile. Studies have also shown that an optimal slope setting correlates with the greatest VT for a given pressure setting.¹⁴⁷ Patient comfort should always be considered in determining optimal slope settings.

Pressure Support Cycle Adjusters

Pressure support breaths have a flow cycling mechanism to terminate the breath. On earlier machines, a set flow termination criterion was usually set by the manufacturer (e.g., 25% to 35% of peak flow). Although this set flow was often effective, it could sometimes terminate breaths too early in patients with long inspiratory demands and it could sometimes terminate too late, typically in patients with obstructive airway disease. In this latter situation, air trapping could also be made worse because of the resulting shorter expiratory time.

There are several approaches to improving cycle synchrony with pressure support. One is to switch from pressure support to a pressure-assist breath (patient-triggered, pressure-targeted, time-cycled breath as is usually available on most machines providing pressure ACV if the set rate is turned low or off). This breath provides direct clinician control of inspiratory time and thus of cycling. Another strategy is to adjust the pressure slope setting described previously on pressure support breaths. A rapid peak initial flow will have a correspondingly high flow cycle variable (and thus short inspiratory time); a very slow peak initial flow will have a correspondingly low flow cycle variable (and thus long inspiratory time).

A newer approach is to allow adjustments of the flow criteria of the pressure support cycle to assure appropriate synchrony of the cycle with the end of patient effort.¹⁴⁸ As with other adjustments of interactive breaths, airway pressure graphics and assessments of patient comfort should guide adjustments. Proper breath synchrony is character-

ized by a comfortable patient without evidence on the circuit pressure graph of continued inspiratory effort after cycling (premature cycling) or of expiratory efforts beginning during the inspiratory phase (delayed cycling). Although no outcome studies have been performed using these cycle adjusters, their physiologic appeal, ease of use, and apparent safety should make them a consideration in virtually every patient receiving pressure support.

Proportional Assist Ventilation

Proportional assist ventilation (PAV) is a novel approach to assisted ventilation in which the clinician sets the “gain” on patient-generated flow and volume.¹⁴⁹⁻¹⁵⁰ In PAV, there is thus no set pressure, flow, or volume. Instead, the sensed patient effort is boosted according to a proportion of the measured work of breathing set by the clinician.

PAV requires that “test breaths” (controlled breaths with fixed flow and volume) be given. This allows for the calculation of respiratory system mechanics, which can be coupled with the measured ventilation to calculate work of breathing (resistive and elastic ventilatory muscle loads). These load calculations are repeated at regular intervals in order to maintain reliable inputs for the PAV algorithm.

PAV breaths are patient-initiated breaths triggered in a conventional way using circuit pressure or flow sensors. Thereafter, the ventilator continues to monitor flow and volume demanded by the patient and puts a clinician-set “gain” on this demand to augment flow and pressure in proportion to the desired reduction in the patient’s work of breathing. The PAV breath cycles when sensed flow demand has ceased.

Like pressure-targeted breaths, PAV flow delivery varies with patient effort; unlike pressure-targeted breaths, pressure also varies with patient effort. The conceptual upside to PAV is that flow and cycle synchrony should be enhanced over conventional flow- or pressure-targeted breaths. Another conceptual upside is that patient-driven tidal volume variability with its theoretical lung protective benefits may be enhanced.¹⁵¹ The downside, however, is that, unlike conventional pressure-targeted breaths, there is no minimum pressure or flow provided. Thus PAV must be used with caution in patients with unreliable ventilatory drives from either disease or drugs. Indeed, with all patients on PAV, careful monitoring and backup support modes should be available.

Most clinical studies with PAV have shown enhanced synchrony compared with conventional modes.¹⁴⁹⁻¹⁵⁶ However, it is not clear what the ideal PAV gain(s) should be in various clinical settings. Moreover, to date, there have been no good randomized trials looking at important outcome benefits (e.g., ventilator duration, sedation needs, mortality) when PAV is compared with conventional assisted/supported ventilation.

Neurally Adjusted Ventilatory Assistance

Neurally adjusted ventilatory assistance (NAVA) utilizes the diaphragmatic *electromyographic* (EMG) signal to trigger, adjust flow, and cycle assisted breaths.^{153,157} NAVA requires placement of a unique esophageal catheter with an array of diaphragm EMG sensors. These sensors detect the onset, intensity, and termination of inspiratory efforts directly.

Like PAV, a clinician-set gain is then applied, which determines flow and pressure delivery in proportion to the EMG signal.

The conceptual benefit to NAVA is that synchrony with all three phases of breath delivery (trigger, gas delivery, and cycle) should be enhanced over conventional flow- or pressure-targeted breaths. Like PAV, another conceptual benefit is that patient-driven tidal volume variability with its theoretical lung protective benefits may be enhanced. Also like PAV, the downside is that there is no minimum pressure or flow provided. Thus, like PAV, NAVA must be used with caution in patients with unreliable ventilatory drives from either disease or drugs. Moreover, with NAVA, there is also concern about the stability of the EMG signal coming from a catheter that can move within the esophagus. Thus all patients on NAVA require careful monitoring and backup support modes.

Most clinical studies with NAVA have shown enhanced synchrony compared with conventional modes.¹⁵⁸⁻¹⁶¹ However, like PAV, it is unclear what the optimal EMG gain setting(s) should be in various clinical settings. To date there have been no good randomized trials looking at important outcome benefits (e.g., ventilator duration, sedation needs, mortality) when NAVA is compared with conventional assisted/supported ventilation.

Key Points

- Positive-pressure breaths are characterized by three variables: the breath trigger, the flow delivery target (pressure or flow), and the cycle criteria.
- The interactions of positive-pressure breaths and respiratory system mechanics are described by the equation of motion: $\text{Pressure} = (\text{flow} \times \text{resistance}) + (\text{volume}/\text{system compliance})$.
- In lungs with collapsed alveoli, alveolar recruitment is accomplished by transient increases in positive-pressure inflation and is maintained by positive end-expiratory pressure.
- Ventilator-induced lung injury can be caused by several mechanisms, including alveolar overdistention and repetitive alveolar collapse/reopening.
- Removing mechanical ventilatory support expeditiously requires regular sedation adjustments and assessments of spontaneous breathing capabilities.

EPIDEMIOLOGY OF NONINVASIVE VENTILATION IN ACUTE CARE

INTRODUCTION

Mechanical ventilation (MV) is a life-saving procedure with applications in acute and chronic respiratory failure. Since the late 1950s, mechanical ventilation has been preferentially delivered by direct access to the lower airways through an endotracheal tube, such as during general anesthesia and surgery, or via a tracheostomy cannula.

Since the late 1980s, home MV has been increasingly applied in patients with chronic restrictive or obstructive respiratory disorders via noninvasive techniques, with the main objective of improving patients' quality of life compared with home tracheostomy. Manufacturers have devoted considerable technologic effort to develop specific home ventilators for "leaky" ventilation and to provide comfortable and adaptable interfaces. The recognition that major sleep disturbances could be caused by abnormal respiration has also contributed to the widespread use of different kinds of home ventilatory support. *Noninvasive ventilation* (NIV) is therefore the standard of care for home mechanical ventilation.

In the early 1990s in parallel with the expansion of home NIV, clinicians started to demonstrate a major interest in this technique as a way of avoiding endotracheal intubation in the acute care setting.¹⁻³ The indications have progressively been extended from acute hypercapnic respiratory failure to a large variety of clinical situations with different degrees of respiratory failure significantly expanding the number of patients currently treated with NIV.^{3a} In the acute care field, technical improvements and specific equipment came late and benefited from improvements made for home ventilation. Currently, there are a number of specific indications for the use of NIV as the standard of care for acute respiratory failure. However, there are also many situations where there is uncertainty about the usefulness or the limits of this technique, explaining large variations in its use internationally (Table 102-1).

Soon after the introduction of invasive MV via a tube in the trachea, many complications of positive pressure ventilation were identified.⁴⁻⁵ These complications generated

concern about the invasiveness of MV. The endotracheal intubation procedure and the tube itself have been implicated in a large number of complications. Some are directly related to the intubation procedure, such as cardiac arrest following endotracheal intubation, and laryngeal or tracheal injury leading to long-term sequelae. Others are related to the fact that the endotracheal tube bypasses the barrier of the upper airway, setting the stage for ventilator-associated pneumonia that carries its own risk of morbidity and mortality. Mechanical ventilation often requires sedation, which itself is often a cause of prolonged weaning and prolonged mechanical ventilation. These major safety considerations prompted the development of noninvasive methods for delivering positive pressure ventilation. Thus, in patients with acute respiratory failure, the main goal of NIV has been—and still is—to provide ventilatory assistance while lowering the risk of adverse events by reducing the need for invasive MV. Convincing evidence that NIV diminishes the risk of infectious complications has been obtained from randomized controlled trials and meta-analyses, as well as from large cohort studies and case-control studies, which have demonstrated substantial decreases in all categories of nosocomial infection.⁶⁻⁸ The reason is that NIV is in general associated with a reduction in the overall invasiveness of patient management: Sedation is usually not required or, if necessary, it is administered at low doses, and the use of central venous lines, urinary catheters, and other invasive devices is reduced compared with patients receiving endotracheal MV⁹ (Fig. 102-1).

Another important factor favoring the use of NIV is the growing number of patients who are unwilling to accept *endotracheal intubation* (ETI) or are considered poor candidates for endotracheal MV because of a fragile underlying health status.¹⁰⁻¹¹ In these patients, NIV offers a chance of recovery with a low risk of complications and can be considered as a ceiling of therapy with acceptable risks. By postponing ETI, NIV may also provide a window of opportunity for the physician, family, and patient to make informed decisions about the goals of therapy in patients treated with palliative care.¹² Potential benefits and risks

Table 102-1 Recommendations for the Use of Noninvasive Ventilation During Acute Respiratory Failure According to Disease and Clinical Status

Recommended	DISEASE			CLINICAL STATUS	
	Intermediate Recommendation	Weak Recommendation	No, or Contraindication	Yes	No
Exacerbations of COPD	Asthma	Mild-moderate ARDS	Severe ARDS	Conscious and cooperative (except encephalopathy in COPD)	Hemodynamic instability
Acute cardiogenic pulmonary edema	Hypoxemic respiratory failure in nonimmunocompromised patients	Community-acquired pneumonia (non-COPD)	ARDS with multiple organ dysfunction	Hypercapnic failure	Loss of consciousness, drowsiness
Acute respiratory failure in immunocompromised patients	Preventive use during procedures (upper endoscopies, endotracheal intubation)	Trauma	End-stage interstitial pulmonary fibrosis	Hemodynamically stable	Abdominal distention, nausea or vomiting
Facilitation of weaning/extubation in patients with COPD	Community-acquired pneumonia in patients with COPD	Extubation failure (non-COPD)	Facial trauma	No multiple organ failures	Uncooperative patient
Postoperative hypoxemia after major abdominal or lung surgery	Extubation failure in patients with COPD	Postoperative preventive following esophageal or lung surgery (using low pressures)	Facilitation of weaning (non-COPD)	Improvement in gas exchange, respiratory, and heart rate within first 2 hr	Inexperienced staff
Acute respiratory failure in patients with obesity-hypoventilation	Postoperative preventive (cardiac, upper abdominal-bariatric surgery)		Undrained pneumothorax		Upper airway obstruction
Do-not-intubate patients	Neuromuscular disease		Upper gastrointestinal bleeding		

ARDS, Acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; ICU, intensive care unit.

Figure 102-1 Noninvasive ventilation in the ICU. Photograph shows a patient treated in the intensive care unit (ICU) by noninvasive ventilation using a face mask covering the nose and the mouth. An ICU ventilator with a double circuit is used. (Written informed consent of the patient was obtained.)

Table 102-2 Potential Benefits and Risks of Noninvasive Ventilation for Acute Respiratory Failure

Benefits	Risks
Unload the respiratory muscles	Intolerance related to interface
Improve gas exchange	Abdominal distention and regurgitation
Decrease left ventricular afterload (in non-preload-dependent patients)	Skin lesions
Decrease right and left ventricular preload	Masking deterioration of underlying disease
Reduce the invasiveness of patient management	Frequent unrecognized patient-ventilator asynchrony
Decrease ICU and hospital stay	May promote large tidal volumes and high transpulmonary pressure swings (potential for VILI)
Diminish the risk of nosocomial infections	
Decrease complications	
Decrease mortality	

ICU, intensive care unit; VILI, ventilation-induced lung injury.

of the technique are discussed later and summarized in [Table 102-2](#).

PATHOPHYSIOLOGY, RATIONALE, AND EXPECTED BENEFITS

CHRONIC OBSTRUCTIVE PULMONARY DISEASE EXACERBATION

Exacerbation of *chronic obstructive pulmonary disease* (COPD) is a common cause of admission to the hospital and *intensive care unit* (ICU). Worsening of dyspnea and symptoms of acute bronchitis are accompanied by rapid and shallow breathing leading to hypoxemia and hypercapnia. Right ventricular failure, encephalopathy, and cardiorespiratory arrest can ensue. The main pathophysiologic pathway

comes from an inability to maintain adequate alveolar ventilation in the presence of major abnormalities in respiratory mechanics. The transdiaphragmatic pressure generated by these patients can be considerably higher than normal and represents a high percentage of their maximal diaphragmatic force, a situation that carries a risk of respiratory muscle fatigue.¹ These changes are accompanied by a high respiratory drive, due to strong stimulation of the respiratory centers by acidosis and hypoxemia. This vicious circle can be modified by NIV, which allows the patient to take larger tidal volumes with less effort, thus reversing the clinical abnormalities resulting from hypoxemia, hypercapnia, and acidosis.^{1,13} The main role of NIV is to allow the patient to increase tidal volume at a lower level of energy expenditure. Ventilatory support working in synchrony with the patient's efforts allows larger breaths to be taken with less effort. As a result of increased alveolar ventilation, *arterial partial carbon dioxide pressure* (arterial PCO₂) and pH

values improve and this, in turn, reduces the patient's ventilatory drive, thereby lowering the respiratory rate and improving dyspnea.

CARDIOGENIC PULMONARY EDEMA

In *cardiogenic pulmonary edema* (CPE), breathing becomes difficult because pulmonary congestion reduces lung compliance, causes hypoxemia and increases the work of breathing. Most patients with CPE improve rapidly with medical therapy. A few, however, develop severe respiratory distress and/or refractory hypoxemia/hypercapnia and require ventilatory support until the medical treatment starts to work. This is particularly common in elderly patients, who may also have a mild degree of chronic bronchitis.¹⁴⁻¹⁵ Several NIV modalities have been used successfully, with the main goal of preventing the need for ETI and/or hastening the improvement provided by medical therapy. The negative swings in intrathoracic pressure increase venous return, while at the same time the negative intrathoracic pressure can impede left ventricular ejection. Respiratory distress and hypercapnia develops, especially if underlying pulmonary abnormalities are present. *Continuous positive airway pressure* (CPAP) and other types of NIV can elevate intrathoracic pressure and reduce the negative pleural swings, decrease shunt, and improve arterial oxygenation and dyspnea in patients with CPE. Interestingly, NIV can substantially lessen the work of breathing and, at the same time, improve cardiovascular function by decreasing left ventricular afterload in non–preload-dependent patients¹⁶ and reduce right and left ventricular preload.¹⁷ In one trial, high-dose nitrate bolus therapy was far more effective clinically than NIV with a low dose of nitrates.¹⁸ It is important to stress the vulnerability of patients with CPE, particularly those with coronary heart disease, and to emphasize that NIV cannot replace adequate medical therapy.¹⁹⁻²⁰

HYPOXEMIC ACUTE RESPIRATORY FAILURE

Unlike exacerbations of COPD or even CPE, hypoxemic *acute respiratory failure* (ARF) represents a heterogeneous group of diseases with different prognoses and treatments. The main common characteristic is hypoxemia, and it is frequently not associated with frank ventilatory failure, at least in the initial phase. Robust large randomized controlled trials are relatively scarce in this setting, and guidelines and recommendations are often not straightforward.²¹⁻²² The heterogeneity of these patients explains some of the contradictory results in the literature, suggesting that the outcome may vary with the study population. The various subgroups of hypoxemic ARF may thus need to be examined separately.

The hallmark of hypoxemic ARF is acute hypoxemia (arterial PO_2/FiO_2 ratio ≤ 300) that necessitates high levels of oxygen and is accompanied by clinical signs of respiratory distress reflecting a high respiratory drive often causing hyperventilation and hypocapnia. The development of hypercapnia is considered a serious late complication, generally indicating impending respiratory muscle fatigue. The rationale for using NIV in hypoxemic ARF is to alleviate the high load imposed on the respiratory muscles (prevention of latent pump failure) and to “treat” hypoxemia (lung

failure). Two specific issues regarding the use of NIV for this indication should therefore be mentioned: (1) NIV is not a cure for the disease and, when interrupted or poorly delivered, the patient immediately returns to the pre-NIV state. In fact, a beneficial effect of NIV on gas exchange and dyspnea may mask disease deterioration. This could lead to life-threatening respiratory failure in case NIV is subsequently interrupted. (2) During the initial phase, patients sometimes are able to cope with the workload imposed on the respiratory muscles with no apparent need for ventilatory support. However, by the time they become completely unable to meet the respiratory requirements, NIV use may be ineffective or even harmful. Therefore there is probably a time and/or a severity window for delivering NIV as a preventive support beyond which its use may become risky²³ (Fig. 102-2).

Moreover, many patients with *acute respiratory distress syndrome* (ARDS) may not be favorable candidates for NIV due to the need for delivering lung protective ventilation. During NIV, high transpulmonary pressure swings and large tidal volumes may be generated, which could lead to the development of *ventilator-induced lung injury* (VILI) and contribute to the poor outcome observed in intubated patients who fail NIV. Most patients with hypoxemic ARF have a high respiratory drive, and it has been shown experimentally that the increased drive caused by a severe metabolic acidosis may cause lung injury.²⁴

In clinical practice, the total pressure delivered during NIV is limited by the leaks that result from high pressures in the mask. To determine the effects of different combinations of pressure support and *positive end-expiratory pressure* (PEEP), the work of breathing and gas exchange was measured in patients with acute lung injury receiving NIV for ARF.²⁵ The highest level of PEEP studied (10 cm H_2O)

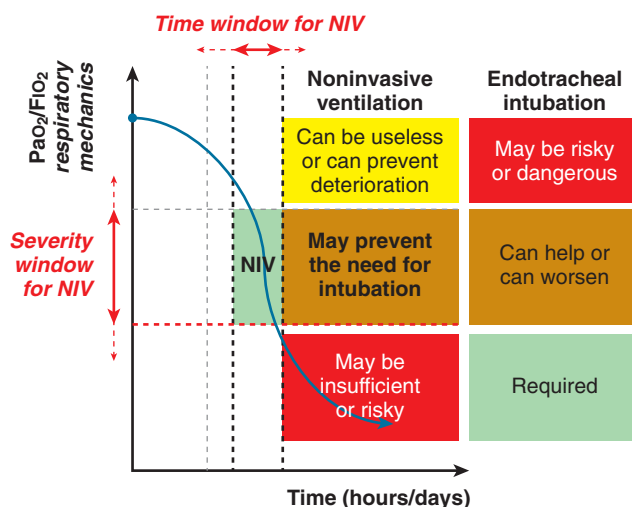

Figure 102-2 The decision windows for noninvasive ventilation (NIV) or endotracheal intubation (ETI). There is an optimal window of time and severity of injury to consider NIV. As a patient worsens over time (see curve of patient course), one must consider whether the severity is appropriate for NIV or ETI. For the right level of severity, NIV can be valuable in offering needed support and perhaps preventing the need for intubation. If the severity worsens further, NIV may be insufficient or risky and ETI is required. If the condition is mild, neither NIV nor ETI would be warranted. Unfortunately, there are no strictly objective criteria which delineate the windows of severity or of time for determining exactly when NIV should be used.

resulted in the greatest oxygenation improvement, but CPAP alone failed to unload the respiratory muscles. Decrease in the work of breathing and dyspnea necessitated the provision of pressure support. To handle the lung and pump failure with NIV, clinicians should provide a sufficient level of PEEP to improve oxygenation, while ensuring an optimal pressure support to unload the respiratory muscles. These two additive but sometimes conflicting pressures generate the peak airway pressure, one of the major determinants of leaks and asynchrony. Patients with poor respiratory mechanics requiring high airway pressures may thus prove difficult to manage with NIV.

PRACTICAL AND TECHNICAL ASPECTS

MODES OF VENTILATION AND SETTINGS

Continuous Positive Airway Pressure and Pressure-Support Ventilation

Continuous positive airway pressure (CPAP) represents the application of a constant level of positive pressure at the airway opening during spontaneous breathing and is widely used in the ICU, particularly in neonates and infants in whom it was first applied. Positive pressure applied at the mouth was shown as early as the 1930s to improve dyspnea in CPE.²⁶ CPAP is not always considered to be a true mode of ventilatory support, but it often provides ventilatory assistance in terms of a patient's work of breathing and oxygenation and achieves the usual goals of ventilatory support. Although there is some debate in the literature, in this chapter, CPAP is considered as a type of NIV. An advantage of CPAP over more complex modes of mechanical ventilatory assistance is that CPAP does not require patient-ventilator synchronization. CPAP results in a higher mean intrathoracic pressure than unassisted spontaneous breathing, with beneficial effects on atelectasis and improvement in oxygenation. Lung compliance can increase, reducing work of breathing, and the presence of *intrinsic PEEP* (PEEPi) can be counterbalanced with a partial reduction of inspiratory effort.

In patients without COPD, CPAP can increase functional residual capacity and may displace ventilation up from the lower flat portion of the respiratory system volume-pressure curve to a more linear portion. Through this mechanism, CPAP can improve oxygenation and respiratory mechanics and potentially reduce the work of breathing.²⁷ L'Her and colleagues²⁵ could not find any significant effect of CPAP on respiratory effort in patients with acute lung injury, in contrast with marked reduction under *pressure-support ventilation* (PSV). Delclaux and colleagues²⁸ evaluated whether CPAP, compared with conventional medical treatment and oxygen alone, reduced the need for ETI in normocapnic patients with acute lung injury. Despite a favorable early physiologic response to CPAP in terms of oxygenation, no outcome benefits were observed. This failure of noninvasive CPAP to provide clinical benefits may be due to the absence of any effect on respiratory effort.

This differs from the results of studies in CPE, in which PSV was comparable or only slightly superior to CPAP alone in terms of the decrease in respiratory effort. In patients

with CPE, CPAP raises intrathoracic pressure, improves oxygenation and dyspnea,²⁹ and lessens the work of breathing.¹⁶ In addition, an increase of intrathoracic pressure decreases transmural pressure of the left ventricle and of the thoracic aorta, reducing left ventricular afterload. Chadda and colleagues found that CPAP and PSV resulted in similar cardiac and hemodynamic effects, by producing similar reductions in right and left ventricular preload mediated by similar effects on intrathoracic pressure.¹⁷

One early clinical trial found more ischemic cardiac events using pressure support than using CPAP, but it was difficult in this small study to differentiate randomization imbalance from true physiologic effects.³⁰ Although these effects were not confirmed in later studies, it raised doubts on its use in patients with ischemic cardiac diseases.³¹

Pressure support is the most frequently used ventilatory mode during NIV.³² In patients with severe hypoxemia, ventilatory support should be able to relieve the dyspnea, improve oxygenation, and decrease the patient's effort to breathe. Combined PEEP and pressure support are needed to achieve these goals. As discussed earlier,²⁵ the compromise between setting PEEP and pressure support during NIV use may be challenging. The total pressure delivered by the ventilator is often reduced to avoid inducing excessive leakage that would complicate NIV administration and impair patient-ventilator synchrony; however, insufficient pressure may translate into unsatisfactory inspiratory muscle unloading.

Asynchronies During Noninvasive Pressure-Support Ventilation

Success of NIV is strongly associated with good clinical tolerance³²⁻³³. Problems of intolerance can be related to the patient, interface, ventilator, and/or ventilator settings. A specific problem during NIV is the presence of leaks around the mask, which may lead to discomfort and patient-ventilator asynchrony, thereby further worsening the clinical situation. Patient-ventilator asynchrony is defined as a mismatch between the patient's neural inspiratory time and the ventilator insufflation time.³⁴ Two types of asynchrony can be directly caused by leaks during NIV with pressure support: prolonged inspiration due to inspiratory leaks³⁵ and auto-triggering due to expiratory leaks. An optimal adjustment of ventilatory settings may improve patient-ventilator synchrony, work of breathing, comfort, and, potentially, the success of NIV.

An observational study used surface diaphragmatic electromyographic activity to evaluate the incidence of patient-ventilator asynchrony in 60 patients during 30-minute sessions of NIV.³⁶ Frequent asynchronies accounting for more than 10% of the respiratory efforts were present in 43% of the patients. Most of these patients were ventilated with an ICU ventilator with no specific "NIV function" activated, which probably contributed to this high incidence.³⁷ Prolonged insufflation due to delayed cycling was the most frequent asynchrony, seen in about 25% of the patients. When large leaks develop during inspiration, the ventilator continues to deliver pressure because the delivered flow remains above the cycling criterion (also referred to as *expiratory trigger value*), so the cycle does not turn off until a time limit is reached. In this situation, the patient attempts to exhale and can fight against the ventilator because the expiratory valve remains closed, generating ineffective

efforts during persistent insufflation. The magnitude of delayed cycling and the number of ineffective breaths are directly associated to the magnitude of leaks.³⁸ This problem is much more prevalent when using an ICU ventilator with no “NIV” mode but may arise also with NIV-dedicated ventilators. Limiting the total inspiratory pressure by reducing the pressure support and/or the PEEP level may be helpful. Persistent leaks indicate a need for limiting the ventilator insufflation time by increasing the expiratory trigger and/or reducing the maximal inspiratory time.^{35,39} Most of the new-generation intensive-care ventilators and many NIV-dedicated ventilators allow adjustment of the expiratory trigger or maximal inspiratory time.

Expiratory leaks can also generate a pressure drop below the external PEEP level or a drop in expired bias flow, simulating the patient’s effort and triggering a ventilator breath. Auto-triggering may promote a short cycle or a flow distortion because the patient does not generate any effort and “fights” the ventilator. NIV-dedicated ventilators have specially designed algorithms that markedly limit auto-triggering.⁴⁰

Other Modalities

Volume-Targeted Ventilation. Volume-targeted ventilation delivers set flow, inspiratory time, and tidal volume with each breath; inflation pressure varies with the intensity of the patient’s effort. Volume-targeted ventilation is rarely used in ARF because it may induce high peak mask pressures, causing discomfort and leaks, risk of gastric distension, pressure sores, and skin necrosis. Controlled modes may, however, be preferred in patients with apnea and hypopnea or unstable ventilatory drive (pressure- or volume-targeted modes), and volume-targeted modes will be preferred in case of unstable respiratory mechanics or failure of pressure-targeted modes to augment spontaneous breathing.

Negative pressure ventilation is available in a few centers in the world. In acute exacerbations of COPD, it seems to provide better outcomes than conventional invasive MV and may be similar to face mask NIV.⁴¹⁻⁴³ The use of a *helium-oxygen mixture* (heliox) for NIV has received much interest because its decreased density leads to decreased resistance in regions with turbulent flow. There were some early promising results in patients with COPD exacerbations.⁴⁴⁻⁴⁵ Unfortunately, large clinical trials were unable to demonstrate a significant clinical benefit when heliox was compared with a conventional gas mixture during NIV.⁴⁶⁻⁴⁷ One possible reason for these negative results is that the rate of NIV failure has progressively declined in the groups treated with standard air-oxygen mixtures, making it more difficult to demonstrate a difference in favor of heliox.

Proportional assist ventilation (PAV) is a physiologically sound mode designed to deliver ventilatory support in response to the patient’s needs.⁴⁸⁻⁵¹ Several studies have compared PAV to PSV during NIV, and the efficacy of the two techniques appears similar.⁴⁹ The largest prospective randomized trial, by Fernandez-Vivas and associates,⁴⁸ was performed in 117 patients with mixed causes of ARF and showed no difference in clinical outcomes between NIV delivered with PSV or proportional-assist ventilation. PAV was more comfortable, and intolerance was less common.

Noninvasive estimation of resistance and elastance are needed for PAV, and leaks make the settings of this mode particularly difficult during NIV.

Neurally adjusted ventilatory assist (NAVA) is based on the detection and quantification of the *electrical activity of the diaphragm* (EAdi) by means of an esophageal array of bipolar electrodes. NAVA uses the EAdi to control not only the timing but also the amount of pressure delivered. The ventilator is triggered, limited, and cycled-off directly by EAdi. Neural control of mechanical ventilation has the capability of enhancing the synchrony between mechanical ventilation and respiratory muscle activity, hence improving patient comfort. Another advantage is that NAVA should not be affected by leaks. Recently, Beck and colleagues showed, in rabbits, that NAVA can deliver assist that is in synchrony and proportional to EAdi even when a “leaky” noninvasive interface was used.⁵² It has also been tested with a helmet, which covers the entire head, in hypoxemic patients after extubation. In 10 hypoxemic patients after extubation, Cammarota and colleagues⁵³ found that NAVA delivered by helmet improved patient-ventilator interaction and synchrony compared with pressure support ventilation. More work needs to be done to determine whether NAVA can maintain adequate levels of ventilator assistance and ensure harmonious patient ventilator interaction in different kinds of respiratory failure.

VENTILATORS

CPAP Systems

Many systems can be used to deliver CPAP. One of the most frequently used consists of a high-flow generator producing an air/oxygen mixture based on the Venturi effect, with an additional source of oxygen and a mechanical expiratory valve. An inspiratory reservoir and a CPAP water valve or a standard mechanical ICU ventilator in CPAP mode can also be used. The Boussignac CPAP device is a small cylindrical plastic adaptor that fits onto a modified face mask. The system uses the incoming flow of oxygen to generate a turbulent virtual pressure valve in the open expiratory side of the mask. The gas is accelerated and circumferentially enters into the open-ended cylinder, generating air entrainment and positive pressure.⁵⁴⁻⁵⁵

ICU or Specific NIV Ventilators

Because ICU ventilators can become less efficient in the presence of leaks,^{57,62} most manufacturers have developed a specifically designed “NIV mode.” This mode detects leaks and automatically adjusts the inspiratory trigger to avoid auto-triggering and the expiratory cycling criterion to avoid prolonged inspiration.⁴⁰ These new NIV modes reduce several of the asynchronies observed during NIV.^{37,40} NIV can be delivered using ICU ventilators or ventilators specifically dedicated for NIV. In a survey from North America of NIV use,⁵⁶ these NIV-dedicated ventilators were the most frequently used ventilators, accounting for two thirds of cases, whereas CPAP generators represented around 30% and ICU ventilators less than 5%. By contrast, a survey in French ICUs found that an ICU ventilator was used in almost 80% of the cases and NIV and home ventilators represented less than 20% of the cases.³²

NIV ventilators perform well in the presence of leaks,⁵⁷ but important differences exist among NIV ventilators.⁵⁸⁻⁶¹ The advantages of ICU ventilators are better monitoring capabilities and the ability to continue invasive mechanical ventilation and full ventilatory support in the event of ETI. No outcome data, such as NIV success or failure, have been shown to be associated with specific asynchronies but, if an ICU ventilator is used, it seems reasonable to use the dedicated NIV algorithm. Adequate patient monitoring may be essential to assess patient-ventilator interaction, detect leaks, and fine-tune pressure levels. A randomized clinical study showed that careful observation of the airway pressure and flow-time curves on the ventilator screen can detect patient-ventilator asynchronies and accelerate arterial PCO₂ normalization and patient adaptation.⁶³ Whether this also ensures higher NIV success rates remains to be determined.

Airway gas conditioning (i.e., the warming and humidification of the inspired gas) constitutes a physiologic procedure performed by the human airway during normal breathing. When the upper airway is bypassed, as during invasive MV, it is necessary to heat and humidify the gas before delivery. During NIV, gas is transferred to the alveoli through the mouth and nose, but the normal airway gas conditioning mechanisms can be insufficient when there are high-flow, high-airway pressure settings and high inspired oxygen fractions. Artificial heating and humidification are usually necessary because inadequate humidification during NIV can cause damage to the nasal mucosa, induction of high nasal airway and possible difficulty with intubation in cases of NIV failure.⁶⁴⁻⁶⁵ ICU ventilators provide much lower levels of humidity compared with turbine or piston NIV ventilators due to the exclusive use of dry gases, and with ICU ventilators, gas humidification is mandatory. Two types of humidification systems can be used: heated humidifiers or heated and moisture exchanger filters. Firm recommendations cannot be made between the two systems—the humidification ability of moisture exchanger filters is reduced in the presence of leaks,⁶⁵ and their internal volume may impose an additional workload by generating carbon dioxide rebreathing. In patients with hypercapnic respiratory failure, this can diminish the ability of NIV to reduce blood carbon dioxide levels and correct respiratory acidosis.⁶⁶⁻⁶⁷ Leaks, however, may reduce the impact of this problem by removing carbon dioxide-rich gas from the mask. A randomized trial did not find any difference in the rate of NIV failure using a moisture exchanger filter or a heated humidifier on ICU ventilators.⁶⁸ A similar problem of carbon dioxide rebreathing may arise when ventilators (using ambient room air), equipped with a one-line circuit, are used with the minimal level of PEEP allowed on these ventilators.⁶⁹⁻⁷⁰

INTERFACES

The interface is an essential component that differentiates NIV from invasive MV. The interface used to connect the patient to the ventilator is usually a full face mask covering both the nose and the mouth. An important distinction concerns leaky masks for single-circuit ventilators versus masks without intentional leaks for double-circuit or for a single circuit equipped with an expiratory valve. New masks

are often made of two or more parts hooked or glued together: a frame made of stiff transparent material and a cushion of soft material to seal the frame against patient face.⁷¹⁻⁷² Improvements have been realized by using different cushions with new materials (such as hydrogel), by improving the fixation system with particular attention to skin and eye care, and by increasing the number of the attachment points permitting a more uniform distribution of pressure.

Masks can be used for the nose or the mouth. Nasal interfaces are available, but their use in ICU patients frequently results in major leakage through the mouth that diminishes the effectiveness of NIV and promotes asynchrony and discomfort.⁷³⁻⁷⁴ There are two existing types of nasal interfaces: nasal masks, designed to cover either the full nose or the nares only, and nasal “pillows” directly inserted into the nostril.⁷⁵ Like oral interfaces, the nasal interfaces are mostly used for chronic NIV.^{71,76} The use of a nasal mask in the ICU leads to mask failure in more than 70% of the patients.⁷⁷ Oral interfaces are associated with significantly more leaks and asynchrony and require better patient cooperation.⁷⁸

Full face masks could be either oronasal or total face; both appear to have similar efficacy and patient tolerance.⁷⁹ Large masks enclosing the entire face or head have been developed.⁸⁰⁻⁸¹ Interestingly, clinical physiologic studies comparing these large masks to standard full face masks have shown comparable efficacy in terms of respiratory muscle unloading, suggesting that the theoretical risk of rebreathing associated with the large internal volume may be small or nonexistent in clinical practice.^{78,82-91} Fraticelli and colleagues⁷⁸ studied the effect of four interfaces—a mouthpiece, a facial mask, and two oronasal interfaces (with small and large internal volume)—on minute ventilation, gas exchange, and work of breathing of patients with acute respiratory failure. Despite large variations in the internal volume of the devices, the authors found no difference in patients’ respiratory effort, arterial blood gases, and breathing pattern.

Helmets, which cover the entire head, have been tested. Use of a helmet was originally proposed for CPAP primarily for patients with acute hypoxemic respiratory failure⁸³⁻⁸⁴; a specifically designed helmet has also been used for NIV.⁸⁵ Helmets may induce more rebreathing than other masks and may be less suitable for patients with hypercapnic respiratory failure.⁸⁶ The helmet requires higher pressures than conventional masks to produce the same efficacy.⁸⁷ Rebreathing with the helmet, compared with other NIV interfaces (two oronasal masks, a total face mask) was studied by Fodil and coauthors⁸²; in this *in vitro* study, the authors showed a large difference between the internal volume of mask (which is about 10 L for the helmet) and the *dynamic effective dead space*, which can be much smaller due to the streaming effect of gases.

The oronasal mask appears to be the best first choice interface. The nasal mask may be comfortable, but because some patients breathe largely through their mouths, outcomes for patients with respiratory distress are usually less favorable. The total/full-face mask has not demonstrated a clear superiority to the oronasal mask in terms of clinical effectiveness and tolerability but is a possible alternative. The helmet can be used as a first-line interface in

experienced hands and for some indications such as pulmonary edema. There is no ideal NIV interface for all patients in all circumstances, and several interfaces should be available at the bedside. With few exceptions (such as the nasal mask and the mouthpiece), interfaces are largely interchangeable in the acute care setting.

INDICATIONS

EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

An international consensus conference published in 2001⁸⁸ recommended that NIV should be considered as the first-line treatment in patients with COPD exacerbations; more recently, different national guidelines advocated this practice.⁸⁹ A Cochrane database review demonstrated that, in these patients, NIV use was associated with decrease in mortality, reduced need for intubation, less treatment failure, faster clinical improvement, and a reduction in treatment complications and length of hospital stay.⁹⁰ The Global Initiative for Chronic Obstructive Lung Disease in 2013 reinforced the importance of NIV when treating COPD exacerbations based on the high success rate (80% to 85%).⁹¹

The first evidence that NIV markedly reduced the need for ETI came from a case-control series reported in 1990.¹ Subsequently, several prospective randomized trials confirmed that NIV reduced the need for ETI and the rate of complications, shortened the length of stay, and improved survival in patients with COPD.⁹²⁻⁹⁸ Studies conducted in the United Kingdom established that NIV was also effective in non-ICU settings.^{92,98} In the largest ICU study, Brochard and colleagues⁹⁹ randomized 85 patients with COPD to treatment with or without face mask PSV. The ETI rate was 74% in the group that received standard medical treatment and 26% in the NIV group. Benefits in the NIV group included a decreased rate of complications during the ICU stay, a shorter length of hospital stay, and, more importantly, a significant reduction in mortality (from 29% to 9%). The overall decrease in mortality was due to reductions in the need for ETI and in various ICU-related complications.

Plant and colleagues¹⁰⁰ conducted a prospective multicenter randomized trial comparing standard therapy alone (control group) to NIV in 236 COPD patients admitted to general respiratory wards for ARF. Treatment failure (defined as fulfillment of criteria for ARF) was more common in the control group (27%) than in the NIV group (15%), and NIV was associated with a lower in-hospital mortality rate. These studies made clear that early NIV should be an important component of first-line therapy of COPD exacerbations to prevent further deterioration.

A recent study used a large database¹⁰¹ and analyzed more than 7 million admissions for acute exacerbations of COPD in the United States from 1998 to 2008, of which 612,650 (8.1%) required respiratory support. The authors showed an increase in the use of NIV (from 1% to 4.5% of all admissions) and a 42% decline in invasive MV (from 6% to 3.5% of all admissions). Intubation and in-hospital mortality declined during this period. By 2008, NIV was used more frequently than invasive MV as the first-line therapy for acute exacerbations of COPD.

A learning curve exists for NIV. In a single-center study by Carlucci and colleagues,¹⁰² the NIV success rate remained stable over the study period but patients treated with NIV during the last few years of the study period had more severe disease, higher arterial PCO₂ levels, and lower pH values. This indirectly reflected that more severe exacerbations could be treated with NIV out of the ICU over the years. In an 8-year study performed in a French university referral hospital, NIV use increased gradually, in step with a decline in conventional treatment with ETI.⁶ In parallel, the nosocomial infection and mortality rates significantly diminished.

NIV for patients with COPD exacerbations can be administered by experienced staff outside the ICU, but it is recommended that the most severely affected patients, such as those with an arterial pH less than 7.30 on admission,¹⁰⁰ should be managed in the ICU. A low pH, marked mental status alterations at NIV initiation, presence of comorbidities, and a high severity score are associated with a higher rate of early NIV failure.³³ A few patients experience late or secondary failure after an initial improvement.¹⁰³ In a recent observational prospective study, the presence of pneumonia and the serum albumin as an indicator of patient's nutritional status were identified as the most important determinants of NIV outcome in COPD patients.^{103a} These patients with late NIV failure (need for intubation after 72 hours or persistent dependence on NIV) may have more severe disease and exhibit sleep deprivation.¹⁰³⁻¹⁰⁴ A longer time from onset of the COPD exacerbation to NIV initiation may also reduce the likelihood of success. Every effort should be made to deliver NIV early, and close monitoring is necessary when NIV is initiated at a late phase, a situation where its use is less effective.¹⁰⁵ Several observational studies and one small randomized trial showed positive clinical results in patients with hypercapnic encephalopathy due to COPD exacerbation and suggested that even at this stage it may be worth trying to "wake up" the patient with NIV.¹⁰⁶⁻¹⁰⁷

A few studies have suggested that NIV use may be associated with higher 1-year survival rates, as compared with standard ICU therapy or invasive MV.^{105,108-110} These studies have a number of methodologic flaws, but the consistency of the results suggests interesting long-term benefits of NIV. Some authors argue for continuing NIV at home after exacerbations. One of the benefits could be a reduction of the readmission rate, as suggested in one small randomized controlled trial.¹¹¹⁻¹¹²

In conclusion, NIV offers many advantages over standard medical therapy and invasive MV to treat exacerbations of COPD and there is strong evidence that NIV is cost effective, being both more efficient and cheaper compared with standard therapy alone.^{22,113}

ASTHMA

NIV can be used in asthmatic patients not responding well to medical treatment, and there is a growing interest in this technique and its combination with aerosol therapy.¹¹⁴ A recent report using a large U.S. database indicated that there has been a substantial increase in the use of mechanical ventilation for acute asthma over the past years, accompanied by a shift from invasive mechanical ventilation to NIV.¹¹⁵ Only a few small randomized trials have rigorously

evaluated the benefits. Two cohort studies found beneficial short-term effects of NIV in asthmatic patients whose condition was deteriorating despite medical therapy.¹¹⁶⁻¹¹⁷ In a randomized trial,¹¹⁸ all patients treated for acute asthma were randomized to either NIV with two different levels of pressure support and PEEP or to oxygen. A greater reduction in dyspnea was observed in the NIV groups compared with the control group. The NIV group with the higher pressure demonstrated a significant improvement in the forced expired volume in 1 second compared with the control group. Two other trials found faster improvement in lung function using NIV with a shorter length of stay or a reduced need for hospitalization.¹¹⁹⁻¹²⁰

EXACERBATION OF OTHER CHRONIC LUNG DISEASES

All forms of acute-on-chronic ventilatory failure share several common pathophysiologic pathways. NIV seems to be an interesting option in patients with restrictive lung disease, especially when respiratory system compliance is still preserved.¹²¹ A recent large cohort study compared the efficacy of NIV in patients with COPD ($n = 543$) and in patients with acute respiratory failure due to obesity hypoventilation syndrome ($n = 173$).¹²² Patients with obesity hypoventilation had fewer late NIV failures, but overall survival adjusted for confounders, length of stay, and hospital readmission were similar in both groups. In patients with COPD, obesity was associated with less late NIV failure and hospital readmission. These data strongly argue for the fact that patients with obesity hypoventilation syndrome can be treated with NIV during an episode of acute exacerbation with similar efficacy and better outcomes than patients with COPD.

CARDIOGENIC PULMONARY EDEMA

Clinical Results

The first evidence of therapeutic efficacy of positive pressure use during acute CPE was shown in 1985.¹²³ Rasanen and colleagues¹²³ randomized 40 patients with acute CPE and respiratory failure to conventional therapy or face mask CPAP of 10 cm H₂O. The interventional group demonstrated better improvement of gas exchange, a decrease of respiratory work, and a tendency to a lower intubation rate. Subsequently, other randomized trials conducted in the emergency department or in the ICU comparing CPAP with pressure support plus PEEP (PSV plus PEEP) with standard therapy found that the two techniques improved arterial blood gases and respiratory rate and significantly reduced the rate of ETI.^{19,124-126}

Recently published guidelines¹²⁷ recommend NIV use in patients with acute CPE, dyspnea, and respiratory rate greater than 20 breaths/min to improve clinical symptoms. Nevertheless, intubation is often the best option in patients with cardiogenic shock and low blood pressure (systolic blood pressure < 85 mm Hg) or altered level of consciousness. In more recent European guidelines, the level of evidence (level B-class IIa) for NIV use to treat acute CPE¹²⁷ was lower than that formerly recommended. This decrease in the level of recommendation was mainly due to the publication of the 3CPO trial,¹²⁸ the largest multicenter con-

trolled study to date. It was performed in the emergency department and evaluated the possible benefits of NIV in acute CPE. Patients admitted with a clinical and radiologic diagnosis of acute CPE, respiratory rate greater than 20 breaths/min and pH less than 7.35 were randomized to conventional pharmacologic therapy plus NIV (CPAP or PSV plus PEEP) or standard oxygen therapy. The study included 1069 patients and showed that NIV was associated with faster reduction in dyspnea, heart rate, and earlier resolution of metabolic abnormalities than standard oxygen therapy. Intubation rates were low and not different between groups (3%), and 7- and 30-day mortality rates (9.8% vs. 9.5% and 16.4% vs. 15.2%) were similar in the control and NIV groups, respectively. The control group was characterized by a high incidence of crossover (15%) to PSV plus PEEP or CPAP. Without this crossover, a much higher rate of intubation might have been observed in the oxygen group. Other study limitations were (1) severely ill patients, who required "lifesaving or emergency intervention," were excluded and might have benefited from NIV; (2) patients had mild hypoxemia; and (3) a low intubation rate was observed.

A more recent multicenter clinical trial of 207 patients with acute CPE¹²⁹ compared oxygen therapy at 15 L/min to 7.5 to 10 cm H₂O CPAP initiated outside the hospital and continued in-hospital in the ICU. The CPAP intervention group demonstrated a significantly greater and faster resolution of clinical symptoms, as well as a lower presence of intubation criteria and a tendency for a lower death rate at day 7, although this last parameter was not statistically different.

Most studies indicating benefits of CPAP or PSV plus PEEP included patients who, on average, had hypercapnia and acidosis indicating acute frank ventilatory failure.^{19-20,124,126} A relatively large multicenter study conducted by Nava and colleagues¹³⁰ in patients with CPE found major benefits of NIV only in the subgroup of hypercapnic patients, with no significant benefits in terms of ETI rate or outcome in the overall population that included both hypercapnic and normocapnic patients. Despite the long use of NIV in CPE and the publication of guidelines, there is considerable heterogeneity among hospitals regarding its clinical application. Notably, it seems that the higher the experience of the hospital in the use of NIV in CPE the greater the benefit in terms of avoiding patient intubation.^{130a}

Choice Between CPAP or Pressure Support Plus PEEP

In clinical practice, CPAP is often considered to be easier to apply compared with pressure support plus PEEP. In some small studies in patients with CPE, PSV plus PEEP was more effective than CPAP regarding improvement in physiologic parameters¹⁷ or rapidity of respiratory failure amelioration,¹³¹ but not different in mortality rate or tracheal intubation. In the 3CPO trial¹²⁸ both modes of NIV (CPAP or PSV plus PEEP) had similar clinical outcomes. Another clinical study comparing both modes of NIV demonstrated similar results.¹³²

In summary, NIV use during CPE seems to be an efficient approach that could reduce mortality, especially in the subgroup presenting with hypercapnia. Conventional medical therapy remains the cornerstone, and NIV, whether it is

performed with CPAP or PSV plus PEEP, should be combined with it as soon as possible. CPAP and PSV plus PEEP seem to have similar effects, both in physiologic end points and in clinical outcome, and CPAP can be recommended as a first-line treatment. PSV plus PEEP may be preferred to CPAP in patients with hypercapnia, often associated with comorbidities like COPD or obesity, who are at increased risk of intubation.

HYPOXEMIC ACUTE RESPIRATORY FAILURE

NIV to Prevent Intubation in de Novo Respiratory Failure

The use of NIV in patients with mixed causes of hypoxemic ARF remains debatable. Contrasting results exist between the benefits observed in short-term physiologic studies and in some randomized controlled trials, as well as the high rates of failure in observational studies and the risk of delaying intubation.¹³³ For instance, one trial in patients with severe pneumonia showed that NIV reduced intubation rate (21% vs. 50%) and ICU length of stay,⁹⁷ but this study is often quoted to stress that this benefit was entirely driven by the subgroup of hypercapnic COPD patients. Other RCTs, in nonhypercapnic patients, did not demonstrate any benefit for this indication.¹³⁴ By contrast, NIV has also clearly been shown to be beneficial in selected patients with a variety of patterns of hypoxemic respiratory failure,^{9,97,135-140} reducing the need for ETI and improving outcomes.^{139,141-143} In this setting, PSV plus PEEP seems much more efficient than CPAP.

In a large randomized controlled trial of patients with hypoxemic ARF, Delclaux and colleagues¹³⁴ showed that the use of CPAP resulted in a greater subjective response and improvement in oxygenation at 1 hour but CPAP did not reduce the need for ETI or improve any clinical outcome. In addition, a few patients suffered from specific complications only observed in the CPAP group, including cardiac arrest at the time of intubation or at the time of mask removal. Antonelli and coworkers¹⁴⁴ showed that NIV using PSV plus PEEP was highly beneficial and associated with fewer adverse effects compared with conventional mechanical ventilation in hypoxemic patients ($\text{PaO}_2/\text{FiO}_2 < 200$ mm Hg). These patients did not have COPD, hemodynamic instability, or neurologic impairment and were randomized when they reached predefined criteria for ETI. Improvements in oxygenation were similar with the two approaches. Despite a 30% failure rate, patients treated with NIV had overall shorter durations of ventilation and ICU stays and experienced fewer complications.

A study performed in three centers by Ferrer and colleagues¹⁴⁰ also included normocapnic patients with persistent hypoxemic ARF and used PSV plus PEEP compared with a standard medical treatment with high-concentration oxygen. Patient selection was rigorous, necessitating clinical cooperation of the patient, no alteration in the state of consciousness, and the absence of organ dysfunction, abundant secretions, cardiac arrhythmias, or ischemia. Patients could have pneumonia, CPE, or immunocompromise. NIV reduced the intubation rate by half and ICU mortality from 39% to 18%. These significant effects were found in the group of patients with pneumonia. Extrapolating

these results to individual patients requires the same careful selection process, with exclusion of patients with contraindications. The presence of shock, loss of consciousness, or major secretions should be considered to be contraindications.

However, observational studies describing the use of NIV in pneumonia have often shown high rates of failure.^{137,145-147} Selection of patients, skills, and experience in the application of NIV and in the decision for intubation may all have contributed to these differences. Great care is required when applying NIV to hypoxemic patients because of the possible disadvantages.^{134,148} In a large observational study on the use of NIV in France, Demoule and colleagues¹⁴⁸ compared the overall results of NIV in patients with acute exacerbation of chronic cardiac or respiratory failure with those with hypoxemic de novo respiratory failure. In the “acute-on-chronic” group, the use of NIV was significantly associated with a better outcome (adjusted OR 0.33). In the de novo group, the use of NIV was not significantly associated with a better or worse outcome. This suggests that NIV should not be used when the risk of failure is high and intubation should not be delayed when clinical signs and symptoms suggest impending NIV failure.¹⁴⁹

In sum, finding which subgroup of hypoxemic patients is highly likely to benefit from NIV with minimal risk is still a field for investigation. The following categories of patients have been more carefully studied.

NIV for ARDS

Observational studies and subgroup analysis of randomized controlled trials identified ARDS as a strong predictor of NIV failure.^{147,150-153} A multicenter survey¹⁵⁴ evaluated NIV as first-line therapy in early ARDS patients and found that a higher severity score and a ratio of arterial PO_2/FiO_2 less than or equal to 175 mm Hg 1 hour after initiation of NPPV were independently associated with NIV failure. This survey showed that, with NIV use, ETI was avoided in no more than 50% of patients, even in experienced centers. A recent small prospective, multicenter, randomized controlled trial¹⁵⁵ included 40 patients with mild ARDS. Fewer patients were intubated in the NIV group compared with the control group, and NIV use was associated with less organ failure. The recent Berlin definition of ARDS suggested that NIV may be indicated only in mild ARDS, and not in severe and moderate ARDS, but also emphasized that the role of NIV in ARDS has to be further evaluated.¹⁵⁶ NIV failure in ARDS patients is highly predictable in case of shock, metabolic acidosis, high severity scores of illness, and a greater degree of hypoxemia.¹⁵³

With the H1N1 pandemic, a large number of patients with severe respiratory failure were admitted into ICUs over the world. Many patients developed ARDS requiring intubation and mechanical ventilation and even extracorporeal membrane oxygenation,¹⁵⁷ but NIV was also used widely in these patients with relatively favorable results, albeit with a high rate of failure.¹⁵⁸⁻¹⁶¹ This aspect is interesting because after the SARS experience, a concern was raised about the risk of viral transmission during intubation or while using NIV ventilation.^{162,163} Viral transmission did not seem to be an issue in the setting of H1N1, but more data are necessary to completely address this issue.

NIV in Immunocompromised Patients

The prognosis of immunocompromised patients with ARF has clearly improved in the past 15 years. Invasive MV was repeatedly identified as an independent mortality predictor in this population, and the potential to reduce infectious complications was a strong rationale for NIV use in immunocompromised patients.^{9,139,141,143} NIV was shown to be beneficial in cancer patients with respiratory failure, and decreased mortality.¹⁴¹ The first randomized trial in hypoxemic ARF after solid organ transplantation assessed the role of NIV in 40 patients⁹: NIV reduced intubation rate from 70% to 20%, ICU length of stay in survivors, and ICU mortality (20% vs. 50%), with no difference in hospital mortality. Another trial confirmed the benefit of a sequential use of NIV at an early stage in 52 immunocompromised patients with respiratory failure and pulmonary opacities.¹³⁹ Intubation rates (46% vs. 77%) and ICU mortality (38% vs. 69%) were reduced in the NIV group. Similarly, early preventive use of CPAP for neutropenic patients with mild respiratory dysfunction prevented subsequent evolution to frank respiratory failure, ICU admission, and the need for intubation.¹⁶⁴

The generalizability of the results coming from expert centers and their applicability to real-life practice has often been discussed.²² In an observational study in Italy, NIV was used in 21% of patients with hematologic malignancies requiring ventilatory support.¹⁵⁰ Despite a high failure rate of 46%, NIV was associated with lower mortality than invasive mechanical ventilation after adjustment using a propensity score. Patients intubated from the beginning had a higher severity score but a lower mortality than patients who failed NIV (50% vs. 61%). A trial of NIV as a first-line intervention in selected immunocompromised patients with hypoxemic respiratory failure appears justified but, as stated in a recent editorial, the message is “don’t push too hard!”¹⁶⁵

In summary, the use of NIV in hypoxemic respiratory failure is supported by a strong rationale. The literature has yielded some conflicting results that probably reflect both the heterogeneity of the underlying diagnoses and some real difficulties in the use of the technique in these patients. Selecting the appropriate patients with pneumonia for a trial of NIV will therefore depend on the experience of the team, on the patients’ cooperation, and on excluding patients with hemodynamic instability, mental status alteration, or abundant secretions.

PREVENTION OF POSTOPERATIVE COMPLICATIONS

Respiratory complications constitute a major cause of morbidity after surgery, and mortality is often related to reintubation and complications of mechanical ventilation. NIV is becoming increasingly popular for the prevention or treatment of postoperative respiratory complications.¹⁶⁶⁻¹⁶⁹

Pathophysiology of Postoperative Respiratory Complications

After thoracic or upper abdominal surgery, the patient’s pulmonary condition can worsen due to residual anesthe-

sia or pain. This is associated with a large reduction in functional residual capacity and transient diaphragmatic dysfunction. Perioperative fluid overload, transfusion-related acute lung injury, inflammation, sepsis, and aspiration may coexist and further worsen respiratory function. Respiratory deficits are maximal in the first hours after surgery and generally recede after 1 or 2 weeks. Because it can restore lung volume, CPAP is frequently used in postoperative patients.¹⁶⁹ Some authors advocate the use of postoperative NIV (CPAP or PSV plus PEEP) for both prophylactic and treatment purposes.^{168,170}

Thoracic Surgery

In the postoperative period following lung resection, pulmonary complications are the leading cause of death. Postoperative MV increases the risk of bronchial stump disruption, bronchopleural fistula, persistent air leaks, and pulmonary infection. NIV was proposed to prevent reintubation, atelectasis, and infection postoperatively after chest surgery.¹⁷¹ Prophylactic use of NIV preoperatively and postoperatively was shown to improve spirometry and oxygenation in 32 patients at high risk of complications after lung resection surgery.¹⁷² Comparable results have been obtained with prophylactic use of NIV following cardiac surgery: The largest study randomized 500 patients scheduled for elective cardiac surgery to nasal CPAP for at least 6 hours or standard care.¹⁷³ The number of pulmonary complications was significantly reduced within the CPAP group, but the reintubation rate was low in both groups. Similar results have been obtained after thoraco-abdominal aortic aneurysm repair.¹⁷⁴

NIV has also been used for the treatment of respiratory failure after lung surgery. Auriant and colleagues¹⁴² performed a controlled trial in which 48 patients with ARF after lung resection were randomly assigned to NIV or standard treatment. NIV significantly decreased the ETI rate (50% vs. 21%) and hospital mortality (13% vs. 38%), mostly by preventing intubation-related complications. A recent multicenter trial, however, was unable to find any benefit of a systematic administration of NIV in obstructive patients submitted for lung resection.¹⁷⁵ Similarly, the beneficial effect of NIV (lower intubation rate) was suggested in patients with ARF after esophagectomy; in addition, there was no increase in anastomotic leakage.¹⁷⁶⁻¹⁷⁷ Because the risk of surgical complications induced by positive pressure ventilation is unclear, it is probably wise to keep airway pressures at the lowest effective level.¹⁷⁶

Abdominal Surgery

NIV can potentially counteract several of the anesthetic and surgical consequences that can explain the high incidence of postoperative hypoxemia after abdominal surgery. Restoring lung volume, preventing atelectasis, improving gas exchange, and decreasing the work of breathing may be achieved through different forms of NIV, including CPAP.¹⁶⁷⁻¹⁶⁹ Squadrone and colleagues¹⁷⁰ showed that early CPAP delivered by helmet in 209 patients with arterial PO_2/FiO_2 less than 300 at 1 hour after elective major abdominal surgery was able to reduce the intubation rate (1% vs. 10%, $P=0.005$), as well as the incidence of pneumonia and sepsis. The ICU and hospital length of stay did not significantly differ. NIV was used in this study with the intention

of preventing overt deterioration and more serious complications, suggesting that early use is ideal.

Jaber and colleagues¹⁶⁷ reported that ETI was avoided in 48/72 (67%) patients treated with NIV for acute respiratory failure after abdominal surgery. Arterial PO_2/FIO_2 ratio increased and respiratory rate decreased only in patients who were successfully treated with NIV and avoided ETI. A similar rate of NIV failure in postoperative patients has also been reported in other observational studies.¹⁷⁸

Trauma Patients

Trauma patients present a high risk of pulmonary dysfunction with subsequent hypoxemic respiratory failure. Compared with a high-flow oxygen mask, the use of NIV has been shown to reduce the intubation rate (12% vs. 40%) and hospital length of stay in a single-center randomized controlled trial of 50 patients with persistent hypoxemia within the first 48 hours after thoracic trauma.¹⁷⁹ NIV may constitute a useful adjunct to manage hypoxemic patients with chest trauma, but adequate analgesia remains of paramount importance in this situation. Larger trials are required to clarify the role of NIV for this indication.

DO-NOT-INTUBATE PATIENTS

NIV is now used frequently in patients in whom intubation is not desirable.¹⁸⁰⁻¹⁸⁶ Several reports have described the effects of NIV in patients with ARF who were poor candidates for ETI because of advanced age, debilitation, or a “do-not-resuscitate” order.^{10-11,180,185-186} This approach to NIV is feasible and well tolerated, with an overall survival rate of 50% to 70%, depending on the patient population.¹⁸⁰⁻¹⁸¹ An important distinction should be made between NIV administered as the upper limit of care versus NIV as part of palliative care to relieve dyspnea at the end of life.^{180,184} Regarding the first indication, NIV offers an interesting possibility to improve a substantial number of patients. Outcomes are better in patients with COPD or pulmonary edema than in purely hypoxemic patients.^{181,183,185} In a large observational multicenter trial, Azoulay and coworkers¹⁸¹ assessed patients’ mortality, health-related quality of life and for patients and relatives, signs of anxiety, depression, and posttraumatic stress at 90 days. They compared patients receiving NIV as a ceiling of therapy with patients with no treatment limitation. Hospital mortality in the do-not-intubate group was 46%, but there was no decline at 90 days in health-related quality of life and there were no differences between the two groups in terms of mental health, anxiety, depression, or posttraumatic stress disorder of patients and their relatives. For NIV used in purely palliative care, we have only limited information on its real benefit.^{182,184}

DURING THE WEANING PROCESS AND POST-EXTUBATION

Weaning

A number of patients with COPD require ETI because they fail NIV, have a contraindication to NIV (such as a need for surgery), or exhibit criteria for immediate ETI. When there

is a need for prolonged ventilatory assistance, these patients can be switched to NIV after a few days of ETI to reduce the time of intubation.^{187,188,188a} This approach was examined in several trials with contradictory results.¹⁸⁷⁻¹⁹⁰ Times to extubation were usually reduced, but this was not consistently translated into a reduction in hospital and ICU stay and mortality.¹⁹⁰⁻¹⁹¹ No difference between early NIV weaning and the standard weaning process was reported in several studies.^{188,192} Complications associated with mechanical ventilation, notably pneumonia and sepsis, were either reduced or remained unaffected by this strategy.¹⁹⁰⁻¹⁹² In the most recent multicenter trial, extubation followed by NIV or extubation followed by standard oxygen therapy were identical with respect to weaning success and reintubation.¹⁸⁹ On the basis of the current evidence, NIV cannot be recommended as an alternative to the standard weaning process.

Post-extubation

NIV has been proposed as a way to minimize reintubations in the approximately 10% to 20% of critically ill patients who fail extubation, even after fulfilling all weaning criteria and having successfully completed a weaning trial.¹⁹³⁻¹⁹⁴ The physiologic rationale for this approach in patients with COPD was well demonstrated by Vitacca and coworkers,¹⁹⁵ who showed equivalent values of the work of breathing under the same ventilatory support delivered before extubation or with NIV after extubation. Several studies addressed the role of NIV in preventing reintubation with unequivocal results.¹⁹⁶⁻¹⁹⁷ When post-extubation respiratory failure has developed, delivering NIV is often futile and, indeed, may delay reintubation and increase mortality, as suggested by a large multicenter trial of Esteban and associates.¹⁹⁷⁻¹⁹⁸ By contrast, early delivery of NIV after extubation to prevent subsequent respiratory failure in patients at risk seems to be useful.^{198a} In patients at high risk of extubation failure, NIV was demonstrated to prevent post-extubation respiratory failure and reintubation in several trials.

A survival benefit of preventive NIV was demonstrated in patients who were hypercapnic during the weaning test.¹⁹⁹⁻²⁰⁰ Intubation rates and mortality have been shown to be reduced in high-risk patients (i.e., older than age 65 with cardiac or respiratory comorbidities).^{196,201} These beneficial effects are not observed if NIV is applied routinely in all extubated patients as shown by Su and coworkers,²⁰² who randomized 406 unselected patients to either NIV or supplemental O_2 mask, early following their extubation. They did not observe any difference in terms of reintubation or mortality rates. In conclusion, in the post-extubation period, NIV can be useful provided the appropriate patient is selected: risk factors for reintubation include underlying cardiac and respiratory disease and/or hypercapnia during the weaning test. NIV should be applied immediately after extubation and before development of respiratory failure.

PREVENTIVE USE DURING PROCEDURES

Bronchoscopy

Flexible bronchoscopy is a relatively invasive procedure with an increased risk of complications in critically ill

patients.²⁰³ Bronchoscopy increases work of breathing in spontaneously breathing patients and leads to a decrease in arterial PO_2 by 10 to 20 mm Hg that can persist or even worsen for a few hours after the procedure. Saline instillation for bronchoalveolar lavage and repeated suctioning can lead to a reduction in end-expiratory lung volume. Several feasibility studies showed that NIV with different interfaces can be useful during bronchoscopy in at-risk patients.²⁰⁴⁻²⁰⁷ NIV can prevent alveolar derecruitment and compensate for the extra work of breathing imposed by the procedure. In a randomized trial of 30 hypoxemic patients, CPAP reduced desaturations and the incidence of respiratory failure necessitating ventilatory support (1 vs. 7 patients in the oxygen group).²⁰⁷ In another trial of 26 hypoxemic patients, during bronchoscopy, arterial PO_2/FiO_2 ratio increased by 82% in the NIV group and decreased by 10% in the standard oxygen group.²⁰⁵ NIV can help to maintain oxygenation in hypoxemic patients undergoing bronchoscopy. This may translate into a reduction of procedure-related intubations, although more studies are necessary to answer this question.

Endotracheal Intubation

Severe hypoxemia during intubation of hypoxemic patients is common, and the standard bag-mask preoxygenation procedure is often not effective. Baillard and colleagues²⁰⁸ evaluated 53 patients with significant hypoxemia (arterial $PO_2 < 100$ mm Hg while on a high FiO_2 mask) who required ETI in the ICU. The patients were allocated to 3 minutes of preoxygenation, before ETI, performed using a nonbreathing bag-valve mask (control group), or PSV plus PEEP (NIV group) used as a preoxygenation method. The NIV group had a statistically significant improvement in pulse oximetry and arterial PO_2 levels with a lower incidence of pulse oximetry saturation values below 80% during the ETI procedure. NIV intolerance requiring its interruption was not observed. A recent review²⁰⁹ proposed that NIV should be

used for preoxygenation and ventilation in patients who cannot reach oxygen saturation greater than 93% to 95% with high FiO_2 .

HOME NONINVASIVE VENTILATION

Epidemiology

Home NIV refers to the long-term (>3 months) daily application of MV in the home setting through a nasal, oral, or oronasal interface.²¹⁰ Prescriptions for home NIV have markedly increased over the past decades as a result of the increasing prevalence of COPD and *obesity-hypoventilation syndrome* (OHS), although home NIV in COPD patients remains a subject of debate (Table 102-3). Major technological improvements in ventilators and interfaces, with a progressive shift from volume-cycled to less expensive, lighter, and often more comfortable pressure-cycled ventilators, have also contributed to accelerating this approach.²¹⁰⁻²¹¹ The EuroVent Survey²¹⁰ studied patterns of home ventilator use in 16 European countries. The prevalence of patients receiving long-term ventilation varied widely among countries, ranging from 1 to 17/100,000 with an average of 6.6/100,000. Similarly, the relative proportion of patients with neuromuscular, thoracic cage, or lung/airway disorders also differed markedly. Neuromuscular and chest wall disorders were the main indications for NIV in northern Europe, whereas NIV for lung/airway disease was more frequent in southern Europe. Because the prevalence of these conditions presumably does not vary substantially, different patterns of home NIV use probably reflect national policies and differences in the allocation of available resources. Although a similar survey is not available for the U.S. population, extrapolation of the same prevalence suggests that more than 20,000 patients are currently using home NIV in the United States.²¹²

Table 102-3 Recommendations for the Use of Home Noninvasive Ventilation During Chronic Respiratory Failure According to the Type of Disease

Type of Disease	Examples	Benefits
RESTRICTIVE DISORDERS	Obesity hypoventilation syndrome Chest wall disorders Kyphoscoliosis Tuberculosis sequelae Neuromuscular Duchenne muscular dystrophy, poliomyelitis sequelae, ALS, cervical spinal cord injury, phrenic nerve paralysis. Rarely: myositis, acid maltase deficiency	Major impact on survival, health care utilization, respiratory and sleep symptoms, quality of life.
OBSTRUCTIVE DISORDERS	COPD Overlap syndrome Bronchiectasis and cystic fibrosis	Insufficient evidence to promote the systematic use of home NIV in stable hypercapnic COPD. One RCT with improved survival at the expense of reduced health-related quality of life. Good evidence to promote positive pressure treatment in overlap syndrome. A "bridge to transplantation" in cystic fibrosis.
OTHER CONDITIONS	Respiratory center depressant drugs, neurologic conditions (Arnold-Chiari, tumors, infection, stroke, or congenital central hypoventilation)	

ALS, amyotrophic lateral sclerosis; COPD, chronic obstructive pulmonary disease; RCT, randomized clinical trial.

This section reviews the pathophysiology of respiratory failure in lung disease, the main indications for home NIV, and provides some details on three major indications (i.e., *neuromuscular diseases* [NMDs], OHS, and COPD). Monitoring of home NIV is also discussed.

Pathophysiology

Chronic hypoventilation develops when the respiratory system is unable to cope with the metabolic production of carbon dioxide as a result of pathologic changes in respiratory drive or respiratory pump failure (e.g., NMD, chest wall diseases), or both, as in patients with OHS. In chest wall and NMD, a typical vicious circle of decline begins with hypoventilation during rapid eye movement sleep, and HCO_3^- retention. As diaphragm dysfunction progresses, hypoventilation appears during non-rapid eye movement sleep and progresses to daytime hypercapnia.²¹³ The clinical course in COPD is more often punctuated with episodes of acute-on-chronic respiratory failure related to chest infections. Therefore aims and targets of home NIV may not be necessarily the same for all disease categories.

Indications for Home Noninvasive Ventilation

Subjects with a condition known to be associated with alveolar hypoventilation should undergo regular workups to determine whether they are eligible for home NIV. Patients should be questioned specifically to see if they have early symptoms suggestive of nocturnal hypoventilation,²¹⁴ such as excessive daytime sleepiness, fatigue, morning headaches, cognitive dysfunction, depression, and dyspnea.²¹⁵ In COPD, an indication for NIV takes into account not only the presence of symptoms of chronic hypercapnia but also the frequency and severity of exacerbations.²¹⁵ Patients should undergo a detailed physiologic assessment to detect nocturnal hypoventilation.

The *American Academy of Sleep Medicine* (AASM) recently²¹⁶ defined hypoventilation during sleep as (1) arterial carbon dioxide (or a surrogate such as transcutaneous or end-tidal PCO_2) > 55 mm Hg for ≥ 10 minutes or (2) an increase in $\text{PCO}_2 > 10$ mm Hg from awake supine value to a value exceeding 50 mm Hg for ≥ 10 minutes. Transcutaneous oximetry²¹⁷ has undergone recent improvements in ease of use and software. It is considered reliable for clinical use and allows for early detection and quantification of nocturnal hypoventilation without requiring arterial blood sampling. In addition to monitoring of early symptoms and detection of sleep hypoventilation, regular assessment of respiratory function and inspiratory muscle strength is essential for the decision to implement NIV electively for the prevention of ARF, especially in NMD. Measuring vital capacity is highly reproducible, and decreases in vital capacity below 50% predicted should lead to further investigations; the threshold may vary according to the underlying neuromuscular disorder. Measurement of supine vital capacity is a sensitive marker of diaphragmatic dysfunction,²¹⁸ and a fall greater than 15% when comparing values sitting versus supine correlates well with orthopnea²¹⁹; a decrease of greater than 20% is highly suggestive of diaphragmatic dysfunction. Inspiratory muscle strength (sniff nasal inspiratory pressure and maximal inspiratory mouth pressure) can be easily assessed with inexpensive portable devices. The former may be easier to perform in

NMD, but both measurements are complementary. A negative pressure lower than -70 cm H_2O for men and -60 cm H_2O for women reasonably excludes significant inspiratory muscle weakness.²²⁰

Special Features in Neuromuscular Disease

The clinical course of respiratory failure in NMD is dictated by the natural history of the underlying condition. Some patients remain stable for decades with reported survival rates greater than 90% at 5 years,²²¹⁻²²² whereas others are slowly progressive or rapidly fatal. Therefore the timing and frequency of clinical evaluation should take into account the underlying neurologic diagnosis. In NMD, an indication for home NIV is based on the reversal of early symptoms of hypoventilation and improvement of *quality of life* (QoL) in patients treated by NIV.²²³ Treating subjects with isolated nocturnal hypoventilation may be warranted. In a randomized controlled trial of NIV in NMD patients with nocturnal hypoventilation and daytime normocapnia,²²⁴ most patients in the control group required initiation of NIV within a few months after documentation of sleep hypoventilation. Those treated by NIV had improved health-related QoL, whereas the others were more likely to be admitted with acute-on-chronic ventilator failure (see also Chapter 97).

Amyotrophic lateral sclerosis (ALS) shares many similarities with other NMDs, but its rapid evolution requires a closer follow-up and more frequent respiratory assessment, usually every 3 months. In a randomized trial, Bourke and colleagues demonstrated that initiation of NIV resulted in a significant survival advantage of approximately 7 months in ALS patients with mild to moderate bulbar involvement with either daytime hypercapnia or orthopnea, but did not improve survival in those with severe bulbar involvement.²²⁵ However, even in the latter patients, some aspects of QoL and sleep-related symptoms were improved by NIV, and it may be considered to be an important component of palliative treatment for individuals with advanced disease.

Special Features of Obesity-Hypoventilation Syndrome

OHS refers to the appearance of awake hypercapnia (arterial $\text{PCO}_2 > 45$ mm Hg) in an obese patient (*body mass index* [BMI] > 30 kg/ m^2) after other causes for hypoventilation have been excluded.²²⁶ Prevalence of OHS is estimated to be between 10% and 20% in patients attending sleep clinics²²⁷ and reaches 50% in patients who are hospitalized and have a BMI greater than 50 kg/ m^2 .²²⁸ Sleep-disordered breathing is not part of the definition of OHS, but the prevalence of *obstructive sleep apnea* (OSA) syndrome may be as high as 90% in this patient group. Although global levels of obesity are rising, OHS frequently goes unrecognized until the onset of acute-on-chronic respiratory failure and admission to the ICU.¹²² Pathophysiologic mechanisms include impaired respiratory mechanics with increased work of breathing, upper airway obstruction responsible for sleep-disordered breathing, and decreased respiratory drive leading initially to sleep hypoventilation before overt daytime hypercapnia.²²⁶

The choice of CPAP or *bilevel ventilatory support* (BVS, i.e., CPAP plus intermittent positive pressure) for the initial management of OHS remains a complex issue, especially when patients present with a stable respiratory status,

despite hypercapnia, and a predominant OSA sleep pattern. Piper and colleagues compared CPAP versus BVS in OHS after exclusion of patients with profound nocturnal desaturations or a arterial PCO_2 increase of more than 10 mm Hg, despite optimal in-lab CPAP titration.²²⁹ Daytime blood gases were improved in both groups without differences after 3 months' treatment. Both groups experienced similar improvements in sleepiness, but BVS resulted in a better subjective sleep quality and psychomotor vigilance performance. In contrast, CPAP alone may not be able to resolve hypoventilation in patients with either a high BMI, severe hypoxemia at baseline, or severe restrictive impairment. For this reason, most experts recommend the use of BVS in the acute setting with consideration of a switch to CPAP after an initial period BVS and correction of hypoventilation. In this case, close monitoring of diurnal arterial PCO_2 is warranted.

During NIV, *expiratory positive airway pressure* (EPAP) and *inspiratory airway positive pressure* (IPAP) can be adjusted individually. EPAP is progressively increased to correct apnea and hypopnea and IPAP to correct hypoventilation. Use of a "spontaneous" versus a "spontaneous/timed" mode with a back-up rate is under debate. The 2012 AASM recommendations suggest that the default setting should be "spontaneous" unless central sleep apnea is documented. Recent clinical data have highlighted the importance of setting a back-up respiratory rate when using NIV in OHS with OSA even without previously documented central sleep apnea. Ventilation using the "spontaneous" mode with no back-up rate in OHS subjects on long-term NIV with a "spontaneous/timed" mode resulted in additional respiratory events, mainly central sleep apneic and mixed respiratory events.²³⁰ Data from a randomized crossover trial comparing standard NIV titration versus average volume-assured pressure support confirm that controlled ventilation, defined as less than 50% of patient-triggered cycles, is associated with improved diurnal arterial PCO_2 , better control of nocturnal hypoventilation, and improved health-related QoL at 3 months in a post hoc subgroup analysis.²³¹

OHS is also associated with increased cardiovascular morbidity related to the metabolic syndrome. Evidence concerning the impact of NIV on this aspect of OHS is controversial. In a highly selected group of OHS patients, home NIV was able to improve some aspects of the metabolic syndrome.²³² Conversely, in a randomized trial with unselected OHS patients, inflammatory markers, endothelial function, and arterial stiffness were not improved after 1 month of NIV, whereas blood gas measures and sleep quality did improve.²³³ Thus it appears that positive airway pressure therapy is only part of a multidisciplinary effort to reduce cardiovascular risk in OHS.²³⁴

Home Noninvasive Ventilation for Chronic Hypercapnic COPD

In contrast to home NIV treatment for patients with restrictive lung diseases associated with chest wall disorders or NMD, evidence for the use of NIV in stable hypercapnic COPD patients remains inconclusive. Two randomized controlled trials failed to demonstrate that home NIV had any impact on survival in COPD patients,²³⁵⁻²³⁶ although early hospital admissions (within 3 months) were reduced in one

trial.²³⁵ Another long-term randomized controlled trial suggested that survival may be improved with NIV combined with long-term oxygen therapy compared with long-term oxygen therapy alone, but at the expense of reduced health-related QoL.²³⁷ A recent meta-analysis concludes that NIV is effective in reducing hypercarbia and dyspnea and improving sleep quality, with no improvement in lung function and an unclear impact on survival.²³⁸ Higher positive pressures were associated with improved gas exchange, whereas lower inspiratory pressures were not. Several experts promote the use of high-intensity, noninvasive positive pressure ventilation (Hi-NPPV, with high inspiratory pressure close to 30 cm H_2O and a high back-up respiratory rate) aiming at a maximal reduction of arterial PCO_2 if improved survival is the target.²³⁹ Despite a high number of mask leaks, Hi-NPPV did not impair sleep quality in a randomized crossover trial.²⁴⁰ However, cautious administration of Hi-NPPV is still warranted in patients with pulmonary hypertension or underlying preexisting cardiac disease because deleterious hemodynamic consequences on cardiac output have been documented.²⁴¹ In summary, current evidence is insufficient to support the systematic use of NIV in stable hypercapnic COPD patients.

Despite the lack of clear evidence, COPD is one of the most rapidly increasing indications for home NIV.²¹⁰ Experts still recommend home NIV in stable COPD patients with either symptomatic hypercapnia (arterial $\text{PCO}_2 > 55$ mm Hg) or an arterial PCO_2 between 50 and 54 mm Hg and frequent episodes of ARF requiring hospital admission and ventilator support²¹⁵ in the hope that this may reduce health care costs.²⁴² Indeed, in a pilot randomized controlled trial with highly selected hypercapnic COPD patients surviving an episode of respiratory failure in the ICU, continuation of home NIV was associated with a lower risk of recurrent hypercapnic ARF.¹¹²

Recent guidelines have emphasized the importance of treating comorbidities that contribute to the overall burden of disease in COPD. OSA is now considered as one of these comorbidities in the latest version of The Global Initiative for Chronic Obstructive Lung Disease.⁹¹ Because COPD is projected to be the third leading cause of death worldwide by 2020²⁴³ and the prevalence of obesity—a major risk factor for OSA—is steadily increasing worldwide, it is not surprising that this overlap syndrome is also projected to increase and worsen COPD outcomes.²⁴⁴ In a large prospective cohort with a median follow-up of 9.4 years, Marin and colleagues demonstrated that the coexistence of COPD and OSA is associated with an increased risk of death from any cause and more hospitalizations for COPD exacerbations.²⁴⁵ Although there are no data from a randomized controlled study, most experts strongly encourage treatment of overlap syndrome with nocturnal NIV therapy. When OSA predominates, CPAP therapy is the most appropriate therapy. When nocturnal hypoventilation is the main pattern, nocturnal PSV plus PEEP should be the first choice.

Importance of Monitoring Home Noninvasive Ventilation

Several reports have shown that patients receiving home NIV may develop patient-ventilator asynchrony, unrewarded inspiratory efforts, unintentional leaks, and periodic breathing and respiratory events of obstructive,

central, and mixed origin.²⁴⁶ These complex events may have a detrimental effect on quality of sleep and control of nocturnal hypoventilation. It is therefore important to propose a stepwise strategy to detect respiratory events of clinical relevance in order to adapt ventilator settings and interface.

Medical history is important, although often nonspecific, and sometimes surprisingly unremarkable, despite significant nocturnal respiratory events. Disease-specific *health-related QoL* (HRQoL) questionnaires may be helpful to assess patient-centered end points as a complement to physiologic monitoring of NIV.²⁴⁷ The Severe Respiratory Insufficiency questionnaire was specifically developed for patients with chronic respiratory failure receiving home NIV and is now available in many languages.

Pulse oximetry remains an important and simple tool to ensure that adequate oxygenation is provided and to detect short recurrent or prolonged desaturations, although low specificity of pulse oximetry tracings during NIV remains a major drawback. In patients with NIV and long-term O₂ therapy, sensitivity of pulse oximetry is markedly decreased. Transcutaneous capnography discriminates between hypoxemia related to ventilation-perfusion mismatch or residual hypoventilation under NIV. Newer devices are reliable, provide a more realistic picture of the overnight transcutaneous PCO₂ trend, and can replace repeated arterial blood samples.²¹⁷ Built-in software of home ventilators provides data about compliance, pattern of NIV use, mask leaks, tidal volume, and rates of inspiratory or expiratory triggering by the patient. Multichannel ventilator modules combining oxygen saturation measurement with estimation of leaks and minute ventilation have been shown to be reliable.²⁴⁸ Unfortunately, the accuracy of estimated minute ventilation and leaks by the ventilator varies from one device to another²⁴⁹ and independent validation studies are still warranted for all commercially available ventilators. Therefore physicians should be aware of differences in the estimation of leaks and tidal volume between home NIV devices.

Finally, the use of noninvasive markers of sympathetic activation is becoming available for clinical use. For instance, pulse wave amplitude reduction is a sensitive marker with a high positive predictive value for the detection of micro-arousals associated with respiratory events during NIV, at least in OHS patients.²⁵⁰ If this technique is validated in other patient groups, it could be useful for assessment of sleep fragmentation and improve scoring of subtle respiratory events with simplified tools, such as home polygraphy (i.e., a home-based sleep study, without the need for a complete, in-lab, sleep study under NIV). Full-night polysomnography is time-consuming, costly, and not always available. However, until alternative monitoring options have been tested with evidence of proven efficacy, polysomnography during NIV remains the gold standard to monitor NIV in experienced centers.

EPIDEMIOLOGY OF NONINVASIVE VENTILATION IN ACUTE CARE

The use of NIV in the acute setting has increased markedly since the first small case-series were published in the

1990s.^{75,251} Three multicenter international observational studies on the use of MV applied in the ICU were performed in 1998, 2004, and 2010 by Esteban and colleagues²⁵²⁻²⁵⁴ in which up to 8000 consecutive patients receiving MV over a 1- or 2-month period were evaluated. The surveys showed that the use of NIV progressively increased from less than 5% to around 15% of all admitted ICU patients, with a consistent success rate and therefore a higher number of patients avoiding the need for intubation. A greater number of patients with COPD or heart failure were also successfully treated with NIV outside the ICU.

Similar observational studies performed in France in 1997, 2002, and 2011^{32-33,181} showed a major increase in NIV use as first-line ventilation support for all ICU patients requiring mechanical ventilatory support (16%, 24%, and 31%, $P < 0.0001$). Importantly, when comparing the three periods, a significant increase of NIV as first-line therapy (52% vs. 35%, $P < 0.0001$) was observed among those patients who were not intubated before or at ICU admission. The French survey published in 2006¹⁴⁸ indicated that pressure support was the most usual ventilatory mode (83%) during NIV (CPAP 8% and assist-control ventilation 7%). The last French observational¹⁸¹ study still showed a continuing increase in the overall use of NIV but, interestingly, with a slight but significant decrease in cases of hypoxemic respiratory failure.

The progressive interest in NIV use can be appreciated by examining the number of articles addressing NIV that have been published. Figure 102-3 illustrates the number of references concerning NIV for ARF or home NIV, review articles, and all types of articles published in the National Center for Biotechnology Information's PubMed from 1989-2013.

Figure 102-3 Published literature on NIV. Evolution of the number of published references in PubMed regarding NIV delivered for acute respiratory failure (clinical trial) and during home NIV (home) over a time period from 1989-2013. Review articles are also shown separately, as well as all articles about NIV.

Key Points

- The use of *noninvasive ventilation* (NIV) in the acute setting has increased markedly over the past decade. National and international multicenter studies have demonstrated that 15% of all admitted patients in intensive care units receive NIV, representing first-line ventilator strategy in 31% to 50% of those requiring mechanical ventilatory support.
- NIV can improve physiologic parameters, relieve dyspnea, reduce the invasiveness of patient management, and improve important clinical outcomes such as intensive care unit and hospital stay, complications, and mortality. There is convincing evidence that NIV diminishes the risk of nosocomial infections.
- The beneficial effects of NIV are best demonstrated in patients with acute exacerbation of COPD and obesity-hypoventilation syndrome. In these settings, NIV is recommended as first-line therapy to prevent further deterioration. Moreover, when combined with conventional medical therapy during acute cardiogenic pulmonary edema, NIV can reduce mortality, especially in the subgroup of patients with hypercapnia.
- Use of NIV in hypoxemic acute respiratory failure is controversial, and patients must be assessed carefully to ascertain which ones may benefit and which ones may be harmed by use of NIV because of a delay in intubation. Moreover, NIV may be useful during the post-extubation process as a preventive tool during the weaning process or during various procedures such as fiberoptic bronchoscopy.
- NIV success is strongly associated with good clinical tolerance. Problems with tolerance can be related to the patient, the interface, the ventilator, and/or the ventilator settings. Mask leaks lead to discomfort and patient-ventilator asynchrony, prolonged inspiration due to inspiratory leaks, and auto-triggering due to expiratory leaks. An optimal adjustment of ventilatory settings may improve patient-ventilator synchrony, work of breathing, comfort, and, potentially, the success of noninvasive ventilation.
- The interface is an essential component for NIV. Oral and nasal interfaces are mostly used for chronic NIV. In the acute care setting, the oronasal mask appears to be the best first choice. The total/full-face mask has not been demonstrated to be superior to the oronasal mask. The helmet can be used as a first-line interface in experienced hands and for pulmonary edema. There is no ideal interface for all patients, and several interfaces should be available at the bedside.
- NIV is the standard of care for home mechanical ventilation. Subjects with a condition known to cause alveolar hypoventilation should be evaluated regularly to determine whether they are eligible for home NIV.

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) is a technique of life support that consists of diverting a fraction of the patient's *blood flow* (BF) through an artificial lung for gas exchange (oxygenation and carbon dioxide [CO₂] removal) and then returning it to the patient. Thanks to improvement in technology and materials and to a deeper understanding of pathophysiology, the indications, timing, and management of ECMO have changed substantially over the years. This chapter introduces the concept of ECMO and discusses its use for respiratory support in patients with *acute respiratory failure* (ARF).

PRINCIPLES OF ECMO

ECMO is a generic term used to describe a number of different techniques used for prolonged artificial cardiac and/or respiratory support. Depending on the returning vessel (venous or arterial), ECMO can be used for cardiac (*veno-arterial bypass* [VA-ECMO]) or respiratory support. For respiratory support, blood can be drained either from a vein (*veno-venous ECMO* [VV-ECMO]) or from an artery (*arterio-venous ECMO* [AV-ECMO]). During VA- and VV-ECMO in which blood is drained from a vein, the blood is withdrawn with the action of a pump, whereas during AV-ECMO, the arterial pressure is the driving force. BF passes through the oxygenator (*membrane lung* [ML]), where oxygen is added and CO₂ removed. The efficiency in CO₂ removal is significantly higher than for oxygenation. Depending on the BF through the circuit, the technique may be used mainly for CO₂ removal (BF < 2 L/min) or for both CO₂ removal and oxygenation (BF up to 5 to 6 L/min). For an appreciation of the different techniques available for respiratory support, it is useful to provide a brief historical perspective.

ECMO INDICATIONS AND TECHNOLOGY: A HISTORICAL PERSPECTIVE

The birth of ECMO dates back to 1939 with the development of the first heart-lung machine by John Gibbon; this culminated in 1953 with the first open heart operation.¹ The first successful use of prolonged ECMO was reported by Hill and colleagues² in 1972 in a 22-year-old patient with *acute respiratory distress syndrome* (ARDS). In the following 2 years, other successful cases were reported. Due to the extremely high mortality rate of ARDS patients at the time, these first reports evoked great interest and were the impetus for the first multicenter randomized clinical trial of prolonged ECMO for adults with ARDS.³ The study, commissioned by the National Institutes of Health, failed to show any survival benefit from ECMO. The reasons for failure of this trial were not clear, but the negative results led to a virtual cessation of laboratory and clinical research on adult ECMO. Fortunately, a number of determined investigators continued studying and improving the technique. Currently, there is a resurgence of interest in ECMO and its clinical application.

Important factors contributing to the maintenance of the interest in ECMO were the encouraging results reported in neonatal respiratory failure. The first successful treatment in newborns was reported by Bartlett and colleagues⁴ in 1976, followed in the subsequent few years with several encouraging case series from different groups.⁵⁻⁷ Two prospective randomized controlled studies were then performed: the first by Bartlett's group in Michigan in 1985,⁸ the second by O'Rourke and coworkers in Boston in 1989.⁹ Both studies were positive and in a few years, ECMO became standard treatment for neonatal respiratory failure.

In adults, major advances came from the pioneering work of Kolobow and Gattinoni,¹⁰ who focused on why the NIH-ECMO trial had failed. At the time, the aim of ECMO was to provide reasonably normal blood gases, essentially buying time for the lungs to heal.¹¹ As such, high ECMO BF rates were necessary to improve oxygenation, and the veno-arterial configuration was the standard. In 1977, recognizing that oxygenation and carbon dioxide elimination were based on different physiologic mechanisms, Gattinoni and Kolobow¹² realized that by removing CO₂ through the membrane lung, ventilation of the *native lung* (NL) could be reduced virtually to zero. They showed that nearly all the metabolic CO₂ production could be removed through an artificial lung using much lower extracorporeal BFs than those required to oxygenate the blood.¹³ On the basis of these observations, in 1979, they developed the concept of *extracorporeal CO₂ removal* (ECCO₂R), proposing the use of a VV bypass configuration instead of the classical VA mode and the use of *low-frequency intermittent positive pressure ventilation* (LFPPV) to allow the lung to rest.¹³ In 1980 Gattinoni and colleagues¹⁴ reported the successful clinical application of this technique, and in 1986 they published the results of the first study on ECCO₂R-LFPPV in 43 patients with severe ARF.¹⁵ Unfortunately, these results were not confirmed by a subsequent single-center, randomized controlled trial conducted by Morris and colleagues¹⁶ in 40 ARDS patients. This second failure led to an almost complete stop of ECMO development in adults, confining its application to newborns. Nevertheless, a few centers around the world continued to apply ECMO in adult patients, with important technical improvements.^{17-21,21a}

At least five reasons have led to the recent resurgence of interest in ECMO:

1. Technical developments. There have been a number of technologic advances that have decreased the complications associated with the earlier application of ECMO. Oxygenators, propelling pumps, and cannulas have all undergone substantial improvements. The available equipment now allows easier, safer, and longer ECMO application. An important factor has been the miniaturization of the whole system, making it possible to use ECMO for interhospital transportation.
2. The *Extracorporeal Life Support Organization* (ELSO). Founded in 1989, ELSO includes most ECMO centers around the world. An important function of ELSO is to maintain a registry of ECMO cases and to provide annual reports provide, which information on ECMO usage, survival rates, and complication rates. ELSO has also developed guidelines that represent the most important reference for ECMO users worldwide.²²
3. The concept of *ventilator-induced lung injury* (VILI) and improvement in ARDS treatment.²³ Recognition that mechanical ventilation, though necessary to preserve life, can exacerbate lung damage eventually contributing to mortality, probably represents the most important advance in ARDS research. Ventilation with high *tidal volumes* (VT)²⁴⁻³⁰ and high distending pressures^{31,32} has been recognized as a major cause of VILI. In the seminal ARDS-Network randomized controlled trial, patients ventilated with a VT of 6 mL/kg of *predicted body weight* (PBW) had a significantly lower mortality than those ventilated with a VT of 12 mL/kg PBW.³⁰ These findings led to the concept of “protective ventilatory strategy,” largely consisting of low VT (6 to 8 mL/kg PBW) and limitation of plateau airway pressures (Pplat < 28 to 30 cm H₂O). It is important to understand that the concept of VILI was not recognized early in the history of ECMO; for this reason, in the two aforementioned ECMO randomized trials, no attention was paid to VT and airway pressures in either treatment group.
4. The *Conventional Ventilation or ECMO for Severe Adult Respiratory Failure* (CESAR) trial.³² The CESAR trial, conducted in the United Kingdom and published in 2009, was the first randomized clinical trial showing a survival advantage of ECMO in adults. Adult patients (18 to 65 years) with severe but potentially reversible ARF (defined as a Murray score ≥3 or uncompensated hypercapnia with a pH < 7.20) were enrolled. Patients randomized to receive ECMO were transferred to the Leicester ECMO center, while controls remained in designated treatment centers. Between 2001 and 2006, 180 patients were enrolled. Survival or absence of severe disability at 6 months was 63% in the ECMO group, comparing favorably with 47% in the control group; the authors concluded that referral of severely hypoxemic ARDS patients to a specialized center able to provide ECMO may increase survival. Two major limitations of the study have been identified. First, not all patients allocated to the ECMO group received ECMO because they died before or during transportation (5 patients) or they improved with conventional treatment after transportation to the ECMO center (17 patients). Second, there was no standardized protocol for mechanical ventilation in the control group, resulting in significantly fewer patients receiving a protective ventilatory strategy. As such, a criticism was that the patients randomized to ECMO were treated in a single specialized center, possibly receiving better care. However, despite these limitations, the results of the study have led to an increase in interest in ECMO worldwide.
5. The H1N1 influenza outbreak. During the 2009 Influenza A (H1N1) pandemic in Australia and New Zealand, 61 patients with H1N1-associated ARDS received ECMO for refractory hypoxemia: survival was 78%.³³ Following the Australian experience, several countries in the northern hemisphere prepared for the pandemic and case series were published reporting survival rates ranging from 68% to 83%.³³⁻³⁹ The British ECMO group recently published a cohort study in which patients with H1N1-associated ARDS referred for ECMO to one of the four adult ECMO centers in the United Kingdom were matched with similar non-ECMO treated patients using data from a concurrent, longitudinal cohort study. Hospital mortality rate of ECMO-referred patients was almost one half of that of non-ECMO-referred patients with all the three matching methods used.³⁶

INDICATIONS FOR VENO-VENOUS AND ARTERIO-VENOUS ECMO

The primary indication for VV-ECMO is hypoxemic respiratory failure in patients with a high risk of mortality.

According to ELSO guidelines, ECMO is indicated in patients with arterial PO_2 (PaO_2)/ FIO_2 less than 80 mm Hg with FIO_2 greater than 90% and a Murray score of 3 to 4.²² Although the evidence backing up this recommendation is weak, similar indications have been suggested by different groups as, for example, in relation to H1N1 patients.^{39a} An important finding, described by several investigators is the association between increased mortality and more days of mechanical ventilation before ECMO institution.^{39b} This observation brings to mind the concept of VILI and suggests the importance of starting ECMO before lung injury has become irreversible. In the past few years, several case reports have been published on the use of VV-ECMO for non-ARDS indications, such as ARF due to severe trauma,⁴⁰ pulmonary embolism,⁴¹ severe asthma,⁴² and as a bridge to lung transplant.⁴³

In comparison, the primary indication for AV-ECMO is hypercarbia in patients with respiratory failure and adequate cardiac function. Because the flow through the membrane lung is from the arterial blood, the ability to oxygenate the blood is less than if the inflow was venous blood; instead, the main value of AV-ECMO is the ability to remove CO_2 . AV-ECMO is discussed later in “Low-Flow CO_2 Removal: Indications and Technology,” under “Arterio-venous CO_2 removal.”

Contraindications to ECMO include advanced age, severe disability, and incurable malignancy. Uncontrolled coagulopathy, major bleeding, and prolonged mechanical ventilation are considered relative contraindications. The decision to start ECMO is made on a case-by-case basis.

MATERIALS NECESSARY TO IMPLEMENT VENO-VENOUS ECMO

Basic components necessary for VV-ECMO are the cannulas for vascular access, a pump to propel the blood, and a gas exchange unit (Fig. 103-1). Compared with the systems commonly used during cardiac surgery, ECMO systems are simpler. A schematic of the minimal requirements for a VV-ECMO circuit is shown in Figure 103-2.

OXYGENATORS

Hollow-fiber oxygenators with a polymethylpentene membrane have become the standard for long-term treatment.⁴⁴⁻⁴⁶ Compared with the original silicon membrane, hollow-fiber oxygenators have a smaller priming volume, higher gas transfer rates, and much lower resistance.⁴⁷ The use of polymethylpentene has also completely resolved the problem of plasma leakage that represented the main limitation to the use and diffusion of polypropylene hollow-fiber oxygenators.⁴⁸ The gas and blood compartments are channeled inside and outside the hollow fibers, respectively. A third compartment for heat exchange is commonly present. Each compartment has an input and an output port.

PUMPS

Similar to the diffusion of low-resistance, hollow-fiber oxygenators, centrifugal pumps have almost completely

replaced roller pumps for long-term applications. Modern centrifugal pumps have a hole in the center of the rotor (Mendler design)⁴⁹ and use a magnetically suspended and driven pump that eliminates stagnation, thrombosis, and heat production, which were common complications of earlier centrifugal pump models.

CANNULAS

Vascular cannulas for ECMO have a thin wall, commonly made of polyurethane, and are often reinforced with wire to prevent kinking or collapse. Venous cannulas have side holes close to the tip or along the last 15 to 20 cm (multi-stage cannulas) to facilitate drainage of blood from the venous system. Modern cannulas have heparin-coated surfaces to increase biocompatibility and reduce activation of the clotting cascade.⁵⁰ Recently, some double-lumen cannulas have become available. The most popular is the Avalon Elite designed by Wang and Zwischenberger.⁵¹ With this cannula, blood is drained from both the inferior and superior vena cava and returned directly into the right atrium. VV-ECMO with a single double-lumen cannula approach is gaining popularity over the traditional configuration with two cannulas.

TUBING

The tubing used for ECMO is made of polyvinylchloride, polyurethane, or silicon rubber. Appropriate connectors, with side ports for standard stopcocks, allow connection between different circuit components. All tubing and connectors surfaces can be coated with heparin and biocompatibility linings to reduce the risk and intensity of the thrombotic and inflammatory reactions triggered by the contact between blood and the artificial surfaces.

CANNULATION FOR VENO-VENOUS ECMO

The technique of choice for VV-ECMO cannulation is the percutaneous approach.^{52,53} This technique, introduced in the late 1980s, has essentially become the standard of care. The main advantages are reduced risk of bleeding, shorter operative time, and easier mobilization and nursing of the patient.

Choice of cannula size and positioning is crucial. As a general rule, the size of the cannula should not exceed two thirds of the vessel diameter. Drainage cannulas should be big enough to ensure adequate flow with relatively low suction pressure, and the holes and tip of the cannula should be positioned in a high-flow vessel. Common sizes for drainage cannulas in adults range from 21 to 28 French. Positioning is important to maximize flow and minimize recirculation. *Recirculation* is the shunting of the returned, oxygenated blood back into the intake for the ECMO. Recirculation will reduce the efficiency of ECMO and also increase the oxygenation of the intake blood so that it no longer reflects the true mixed venous oxygen saturation.

Veno-venous bypass may be accomplished using three different configurations: femoral-jugular, jugular-femoral,

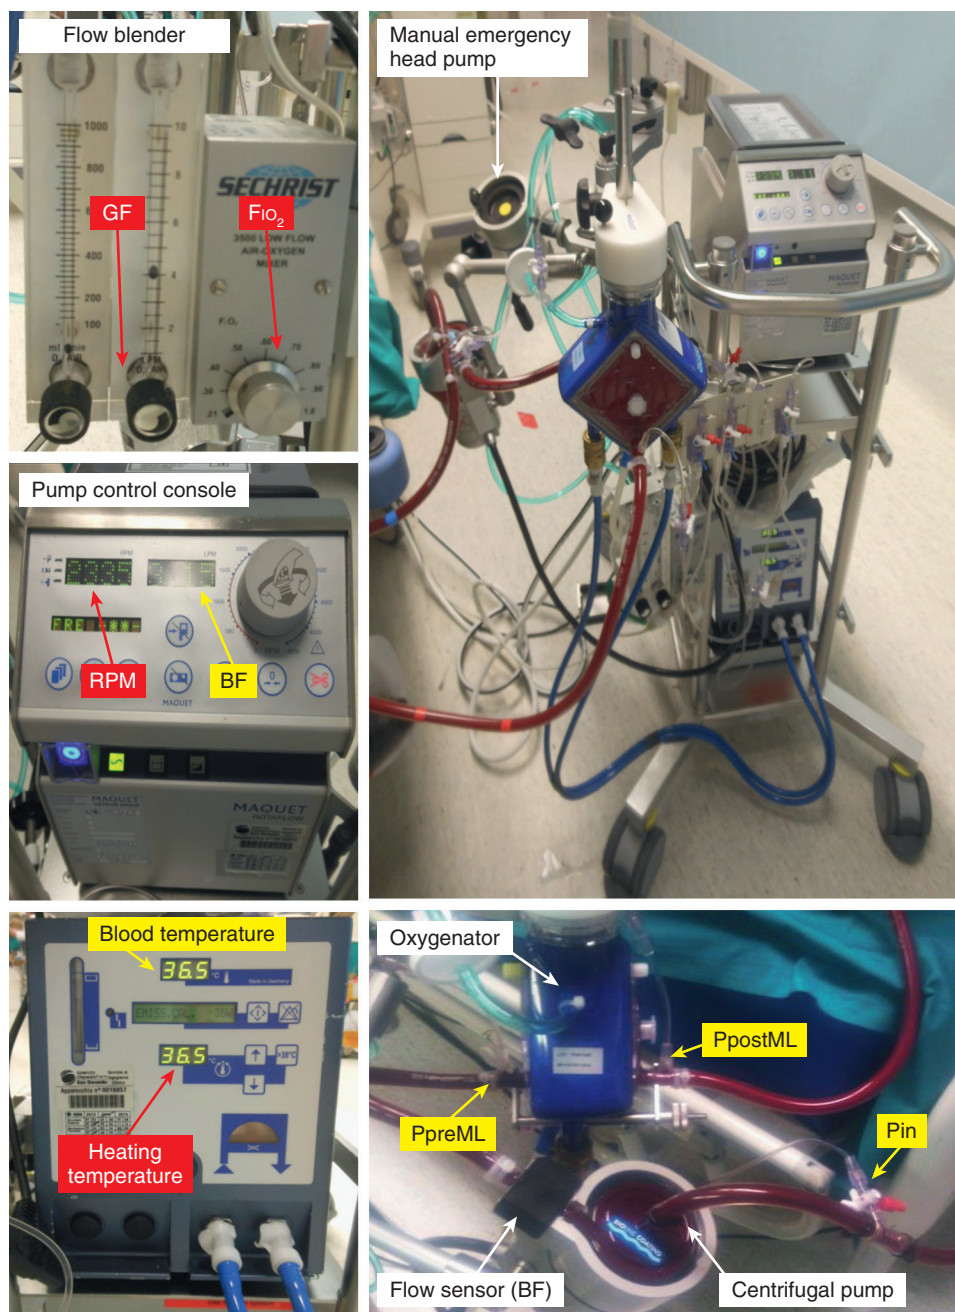

Figure 103-1 Pictures of the main hardware components of an extracorporeal membrane oxygenation (ECMO) unit. Yellow tags show main measured variables: blood flow (BF); temperature of blood drained from the patient (Blood temperature); drainage pressure (Pin); pressure before the oxygenator (PpreML); and pressure after the oxygenator (PpostML). Red tags show main ECMO setting parameters: speed of the centrifugal pump (RPM); sweep gas flow (GF); oxygen fraction of GF (FiO₂); heating temperature.

and femoral-femoral. Factors to consider when choosing the configuration are the drainage capability, recirculation risk, patient mobilization, and complications. The *femoral-jugular* access is the more frequently used; with a correctly positioned femoral cannula of 23 to 25 French, BF rates up to 6 to 7 L/min are easily obtained with minimal recirculation. The *jugular-femoral* approach, in which blood is drained directly from the right atrium, likely provides the best drainage but there is a high degree of recirculation, which can effectively nullify the drainage advantage. The *femoral-femoral* approach offers safer access with less possibility of accidental cannula dislocation; mobilization of the patient's

head is facilitated at the expense of lower limb mobilization. With this approach, however, minimization of recirculation requires careful positioning of the cannula tips, which is generally more difficult to obtain than with other approaches. The tip of the femoral drainage cannula should be positioned in the inferior vena cava superior to the renal veins, approximately at the level of L1-L2 lumbar vertebrae.

Double-lumen cannulas are commonly placed through the right internal jugular vein. To obtain blood flow rates comparable with those commonly achieved with the traditional two-cannula configurations, insertion of cannulas up to 31 to 35 French may be necessary.

Figure 103-2 Schematic of a basic circuit for veno-venous ECMO (VV-ECMO). From the drainage to the returning cannula, a basic circuit for VV-ECMO includes a connector with stopcock for drainage pressure monitoring (pre pump pressure or P_{in}); the centrifugal pump; a flow sensor for monitoring blood flow (BF); a connector with stopcock for monitoring pressure and sampling for gas analysis of the input blood (pre membrane lung [ML] pressure); the membrane lung oxygenator (ML) (inlet and outlet port for blood, sweep gas, and heating water are represented); a connector with stopcock for monitoring pressure and obtaining samples for gas analysis of blood leaving the oxygenator (post membrane [ML] lung pressure).

Choice of the cannulas is also based on the clinical indication. For more severely hypoxemic patients, larger cannula sizes and configurations allowing higher blood flows should be selected from the beginning. Insertion of a second drainage cannula, an upgrade from a single- to a double-cannula configuration, or a switch from VV- to VA-ECMO is sometimes mandated by changes in the patient's needs.⁵⁴

PATIENT-MACHINE INTERACTION DURING VENO-VENOUS ECMO

The effect of VV-ECMO on arterial blood gas values is a function of the complex interplay among different factors. It is useful to discuss the effects on oxygenation and on CO_2 removal separately.

EFFECT OF VENO-VENOUS ECMO ON OXYGENATION

During VV-ECMO, the membrane lung and native lung are in series (Fig. 103-3). We can understand the physiology of VV-ECMO by following the changes in blood O_2 content from the vena cava ($CvCO_2$) to the arterial side (CaO_2). $CvCO_2$ is a function of CaO_2 , cardiac output (CO), and arterial-venous O_2 difference ($CaO_2 - CvCO_2$). A fraction of the venous return (BF/CO) is diverted through the membrane lung. The oxygen delivery of the membrane lung is given by $\dot{V}O_{2ML} = BF \times (CO_{2out} - CO_{2in})$, where CO_{2in} and CO_{2out} are the oxygen content of the blood, respectively, entering (input) and leaving (output) the membrane lung. The oxygen content of the blood returning to the lung (the mixed venous blood,

$\bar{C}\bar{V}O_2$) is the flow-weighted average of CO_{2out} and $CvCO_2$: $\bar{C}\bar{V}O_2 = (CO_{2out} \times BF + CvCO_2 \times [CO - BF]) / CO$. In practice, the resulting effect of the membrane lung is to increase the O_2 content of the blood returning to the lung from $CvCO_2$ to $\bar{C}\bar{V}O_2$. $\bar{C}\bar{V}O_2$ is then increased to CaO_2 by the residual oxygenating capacity of the patient's lung. The oxygen delivery of the native lung is $\dot{V}O_{2NL} = CO \times (CaO_2 - \bar{C}\bar{V}O_2)$, and the patient's total oxygen consumption is simply the sum of membrane lung and native lung oxygen delivery: $\dot{V}O_2 = \dot{V}O_{2ML} + \dot{V}O_{2NL}$.

Besides the oxygenation capability of both the membrane lung and patient's lung, the main determinants of blood O_2 content are hemoglobin saturation and hemoglobin concentration. Once the hemoglobin has been saturated, the only way to increase O_2 delivery and O_2 transport is by increasing the hemoglobin concentration (Fig. 103-4, left panel).^{54a}

Under VV-ECMO, arterial oxygenation will depend on the sum of the partial effects of $\dot{V}O_{2ML}$, mixed venous SO_2 , and $\dot{V}O_{2NL}$.

O_2 Delivery by the Membrane Lung ($\dot{V}O_{2ML}$)

The amount of oxygen delivered by the membrane lung depends on three main factors (see Fig. 103-4).

1. The intrinsic performance of the membrane lung. The oxygenator's oxygenation capability will depend on the membrane diffusion characteristics (thickness, material) and the membrane surface area (see Fig. 103-4, left panel).
2. The O_2 pressure gradient between the sweep gas flow and the blood. On the gas side, the O_2 partial pressure depends on the FIO_2 of the sweep gas. It is important to understand that, similarly to natural lung physiology,

Figure 103-3 A schematic of a model of O_2 delivery and consumption during VV-ECMO. The main determinants of blood oxygen content (mL/dL) from venous return (content in vena cava [C_{vc}]) to arterial blood oxygen content (C_a) are represented. The oxygen content of the blood entering the native lung (mixed venous blood [C_v]) is determined by ECMO BF relative to the patient's cardiac output (CO). Oxygen content in arterial blood (C_a) is determined by the intrapulmonary shunt (shunt) relative to CO. Oxygen content of the blood entering the membrane lung (C_{in}), blood exiting the membrane lung (C_{out}), and blood exiting normally functioning regions of native lung (C_c) are also represented, as well as the oxygen delivery of the membrane lung (mL/min) ($\dot{V}O_{2ML}$), oxygen delivery of the native lung ($\dot{V}O_{2NL}$), and total patient's oxygen consumption ($\dot{V}O_2$). A more detailed description is provided in the text.

Figure 103-4 Oxygen delivery of the membrane lung ($\dot{V}O_{2ML}$, mL/min) as a function of ECMO (BF, L/min) (left panel) and oxygen saturation of the blood entering the membrane lung (SO_{2in} , %) (right panel). The effect of the hemoglobin (Hb) concentration and of the membrane lung surface area (m^2) is represented in the left panel. The formula for computation of $\dot{V}O_{2ML}$ is shown. CO_{2in} , SO_{2in} , and PO_{2in} are the oxygen content (mL/dL), saturation (%), and partial pressure (mm Hg) of the blood entering the membrane lung (ML); CO_{2out} , SO_{2out} , and PO_{2out} are the oxygen content, saturation, and partial pressure of the blood leaving the ML.

the transfer of O_2 through the membrane lung is governed by the ventilation/perfusion matching. However, once a high level of partial pressure has been reached in the outlet blood, further increase in gas flow will not lead to any major increase in O_2 delivery. On the blood side, the higher the oxygen saturation of incoming blood (SO_{2in}), the lower the quantity of O_2 that can be added to the blood (see Fig. 103-4, right panel). As described earlier, an important factor that may result in a high

SO_{2in} is recirculation (i.e., blood already oxygenated from the membrane lung sucked back into the ECMO circuit).

3. ECMO blood flow. Up to a determined blood flow, $\dot{V}O_{2ML}$ will increase directly with the increase in ECMO flow. However, depending on the membrane surface area and the membrane lung characteristics, there is a limit to the oxygenator flow ("rated flow") above which no more O_2 can be added to the blood (see Fig. 103-4, left panel).

Mixed Venous Blood Oxygenation ($\bar{S}vO_2$)

During VV-ECMO, the main determinants of *mixed venous oxygen saturation* ($\bar{S}vO_2$) are the oxygen saturation of the blood leaving the organs and the ratio between extracorporeal BF and CO (Fig. 103-5). At a given CO, the increased oxygenation contribution of the membrane lung resulting from an increase in BF will always lead to an increase in $\bar{S}vO_2$ and *arterial oxygenation saturation* (SaO_2). In contrast, when CO changes at constant BF, the effect on $\bar{S}vO_2$ and SaO_2 is primarily dependent on the level of BF, $CvcO_2$, and

Figure 103-5 Oxygen saturation of blood entering the patient's lung ($\bar{S}vO_2$, continuous lines) as a function of the blood flow (BF)/cardiac output (CO) ratio, at different CO with constant oxygen consumption. At constant CO, increase of BF/CO through increase of BF results in increase of $\bar{S}vO_2$ by two mechanisms: first, because a higher fraction of venous return is oxygenated by passing through the membrane lung; second, because the resulting increase in arterial O_2 saturation will lead to an increase of oxygen saturation of the blood in the vena cava ($SvcO_2$) and therefore in the input (SO_{2in}). The effect of changing BF/CO by changing CO at constant BF (iso BF lines) is also represented. At a constant BF, an increase of CO can have contrasting effects on $\bar{S}vO_2$: An increase in CO increases $SvcO_2$ and SO_{2in} , but the increase in CO also decreases the fraction of venous return oxygenated through the membrane lung. The former effect prevails at lower BF (iso BF line 1 L/min) and the latter at higher BF (iso BF line 4 L/min). Note, at the higher BF (iso BF line 4 L/min), an increase in CO (from 5 to 12 L/min) results in a decrease in $\bar{S}vO_2$ (from 98% to 92%).

recirculation. A decrease in CO is associated with a parallel decrease in $CvcO_2$. Below a certain value of $CvcO_2$, the expected positive effect on oxygenation of the increase in the BF/CO ratio may be offset by the decrease in $CvcO_2$, resulting in a net decrease of $\bar{S}vO_2$ and SaO_2 . At BF commonly used in clinical practice (3 to 5 L/min), an increase in CO is commonly associated with a decrease in the oxygenation contribution of the membrane lung, resulting in a decrease in $\bar{S}vO_2$ (see the iso BF line with 4 L/min in Fig. 103-5) and ultimately a decrease in SaO_2 (Fig. 103-6C). Conversely, at lower BF (1 to 3 L/min), and at critically low arterial oxygenation, an increase in CO is associated with an increase in both $\bar{S}vO_2$ (see the iso BF line with 1 L/min in Fig. 103-5) and SaO_2 (see Fig. 103-6C). These relationships are the basis for the manipulation of BF and CO during VV-ECMO. However, there are limitations to how much the BF/CO ratio can be increased. First, in the presence of recirculation, either an increase in BF or a decrease in CO will increase the amount of recirculating blood, thereby blunting the expected positive effect on oxygenation. Second, an increase of BF is limited by the cannula size and blood volume status of the patient. Third, oxygen delivery to peripheral organs depends on both CaO_2 and CO; at low oxygenation levels, a higher CO is necessary to ensure sufficient organ oxygenation.

Oxygen Uptake from the Native Lung ($\dot{V}O_{2NL}$)

The native lung will contribute to arterial oxygenation by adding oxygen to the $C\dot{V}O_2$ according to its residual gas exchange capability, which depends on the severity of the lung disease (i.e., the intrapulmonary shunt fraction) (see Fig. 103-6A) and is heavily influenced by the ventilator management (see Fig. 103-6B) and cardiac output (see Fig. 103-6C). The main goal during VV-ECMO is to reduce and limit all the factors that may contribute to VILI, namely high ventilation volumes and pressures and high FiO_2 . However, a decrease of FiO_2 , *positive end-expiratory pressure* (PEEP), and/or minute ventilation may temporarily lead to worsening of gas exchange function of the native lung, increasing the reliance of patient oxygenation on ECMO effectiveness. Thus, the expected level of BF and indeed the choice of ECMO equipment and cannula sizes will be strongly influenced by the native lung management and,

Figure 103-6 The effect of ECMO blood flow (BF) on the partial arterial pressure of oxygen (PaO_2). As BF increases, the PaO_2 rises; the degree of increase also depends on native lung function (intrapulmonary shunt, shunt) (A), the fraction of oxygen at the ventilator (B), and the cardiac output (C).

Figure 103-7 Oxygen delivery ($\dot{V}O_{2ML}$) and carbon dioxide removal ($\dot{V}CO_{2ML}$) as a function of ECMO blood flow (BF). Curves have been mathematically derived assuming a CO_2 removal efficiency of 40% with a P_{aCO_2} of the input blood of 60 mm Hg and complete equilibrium of partial pressure of oxygen between the blood and gas compartments. The operative range of BF of the major CO_2 removal techniques is represented. $AVCO_2R$, arteriovenous CO_2 removal; $LF-ECO_2R$, Low-flow CO_2 removal; PALP, pump assist lung protection; $VV-ECO_2R$, VV -classical VV -ECMO with different oxygenator sizes and operative BF.

most importantly, by the level of oxygenation that is considered clinically acceptable.

EFFECT OF VENO-VENOUS ECMO ON CO_2 REMOVAL

With any type of membrane lung, clearance of CO_2 is always more efficient than oxygenation (Fig. 103-7). Although the amount of O_2 delivery is limited to that which fully saturates arterialized blood, there is no specific limit to the amount of CO_2 that can be removed from venous blood. Most of the CO_2 is transported in blood in the form of bicarbonate ion. CO_2 transport in blood is defined by a high content at a relatively low partial pressure (40 to 50 mm Hg under normal conditions). Normal venous blood carries at least 50 mL of CO_2 / 100 mL. This means that half a liter of venous blood contains an amount of CO_2 equivalent to roughly the entire CO_2 production per minute of the body (≈ 250 mL/min for a 70-kg normothermic man). Thus, the entire patient CO_2 production can theoretically be removed with low BF provided that a high gas flow is used. At high sweep gas flow (8 to 15 L/min), the CO_2 concentration in the gas compartment remains close to 0 mm Hg and a high CO_2 pressure gradient is maintained. For example, at a normal bicarbonate ion concentration, a liter of blood can contain up to 500 mL of CO_2 . With the removal efficiency of current technology (about 20% to 40%), up to 200 mL of CO_2 per minute may be removed with an extracorporeal BF of 1 L/min. The strict relationship between $\dot{V}CO_{2ML}$ and gas flow is advantageous because it allows dissociation of CO_2 removal from oxygen delivery. In other words, we can use the gas flow to control CO_2 removal and can use extracorporeal BF to control oxygen delivery.

This removal of a large percentage of the CO_2 production allows the clinician the option of decreasing the minute

ventilation delivered by the ventilator. If 50% of $\dot{V}CO_2$ is removed by the membrane lung, minute ventilation of the native lung can roughly be halved. This is the physiologic basis for the use of ECMO to provide a more protective ventilation strategy, as discussed later.

MONITORING AND MANAGEMENT OF THE ARTIFICIAL LUNG

Management of ECMO is essentially based on setting three variables:

1. Device blood flow. As we have seen, extracorporeal BF is the main determinant of patient oxygenation and should be set to the lowest level that provides adequate oxygenation. The required flow will be a function of the target oxygenation level and the ventilator strategy applied to the native lung.
2. Gas flow. The main determinant of CO_2 removal by the ECMO device is the sweep gas flow; consequently, gas flow determines the minute ventilation needed from the ventilator.
3. FIO_2 of sweep gas. It is generally set to 1.0 and progressively decreased as soon as the patient's clinical condition improves.

The ECMO circuit should be monitored several times daily (at least once daily by a perfusionist). Careful monitoring of the ECMO system is aimed at answering the following questions:

1. Is the oxygenator performing well? If the FIO_2 of the sweep gas is 1, the expected PO_2 in the output blood (PO_{2out}) should be high (generally > 300 to 400 mm Hg). The PO_{2out} is usually higher than 500 mm Hg at lower blood flows and starts to decrease as flow increases to the rated flow for that type of oxygenator. Accounting for this effect, daily monitoring of the PO_{2out} allows detection of any decrease in oxygenator performance, which may prompt a circuit substitution. In addition, as the oxygenator performance worsens, increasing gas flow rates are necessary to maintain the same P_{aCO_2} .
2. Is drainage effective? Efficient blood drainage is crucial. Drainage effectiveness can be assessed by monitoring the pressure in the tubing proximal to the pump (suction pressure [P_{in}]) (see Figs. 103-1 and 103-2), and the BF/revolutions per minute (RPM) ratio: if drainage is insufficient, BF becomes unstable (sudden drops) and excessive suction pressure can cause "kicking" or "swinging" of drainage lines. P_{in} is an essential variable that should be monitored. Appropriate drainage cannula size and device blood flow should be selected to avoid excessively negative P_{in} . Values of P_{in} should be less negative (i.e., closer to zero) than -100 mm Hg. When drainage becomes less effective, P_{in} will become more negative, BF will decrease, and higher revolutions per minute of the pump must be set to maintain the same device BF. The commonest reason for a reduction of drainage effectiveness is a change in patient blood volume status and/or a decrease in venous BF proximal to the cannula tip. Volume expansion and temporary reduction of the extracorporeal BF are the easiest

solutions. It is always important to check for any change in cannula position, tube kinking, or obstruction.

- Is there thrombosis in the circuit? The oxygenator is the main site of activation of thrombosis. Clot formation in the oxygenator may be detected by daily inspection of oxygenator surfaces, by monitoring the transmembrane pressure (difference between post (PpostML) and pre (PpreML) oxygenator pressure), and by monitoring coagulation parameters (see later).

VENTILATORY MANAGEMENT OF THE NATIVE LUNG

The main objective during VV-ECMO is to ensure adequate gas exchange while minimizing VILI.²⁴ Optimal setting of the mechanical ventilator during ECMO is still a matter of debate, and strategies may vary from center to center.^{54b} An example of daily ventilatory management in an ARDS patient on VV-ECMO is presented in Figure 103-8. When ECMO is instituted, patients are generally sedated, paralyzed, and ventilated with relatively high ventilatory pressures, high respiratory rates, and an FiO_2 of 1. The first steps after initiating ECMO are to decrease the respiratory rate (e.g., to 8 to 15 bpm) and eventually lower V_T to 3 to 6 mL/kg PBW.^{32,37,39} This approach is made possible by the concomitant slow increase of gas flow. FiO_2 delivered by the ventilator is decreased to reduce oxygen toxicity and decrease the risk of resorption atelectasis.

All centers agree that plateau pressure should be kept below 25 to 30 cm H_2O ,²⁹⁻³² but there is less agreement

about how to set PEEP. Some centers suggest rapidly reducing PEEP to 10 to 15 cm H_2O ,³² whereas others suggest keeping PEEP unchanged or even increasing it.²² This is the dilemma: whether to let the lungs collapse or try to keep them open.⁵⁵⁻⁵⁹ Centers with greater expertise often apply different approaches in different patients or may even change the ventilatory approach in a given patient according to changes in clinical status. The ventilatory strategy has a big influence on the level of extracorporeal BF and gas flow necessary to maintain adequate oxygenation. In addition, if the residual gas exchange capability of the native lung is poor, a higher device BF and a larger cannula size will be necessary. As soon as the lung function and the patient's clinical condition improves, the patient may be switched from controlled to assisted mechanical ventilation. The current approach is to promote early mobilization. During this phase, oxygenation may not be a major problem anymore and it would now be possible to manipulate gas flow to modulate the patient's respiratory drive and effort.

Monitoring of native lung function may be difficult during VV-ECMO, and there is a paucity of data in the literature and guidelines on how to accomplish this. In many centers, a pulmonary arterial catheter is routinely used, allowing continuous measurement of SvO_2 that, as explained previously, provides an objective measure of the relative contribution of the membrane lung to systemic oxygenation. It also allows one to compute the intrapulmonary shunt fraction; during VV-ECMO, the intrapulmonary shunt fraction is probably the physiologic variable that best assesses native lung gas exchange capability while being least affected by the presence of ECMO. Finally, the

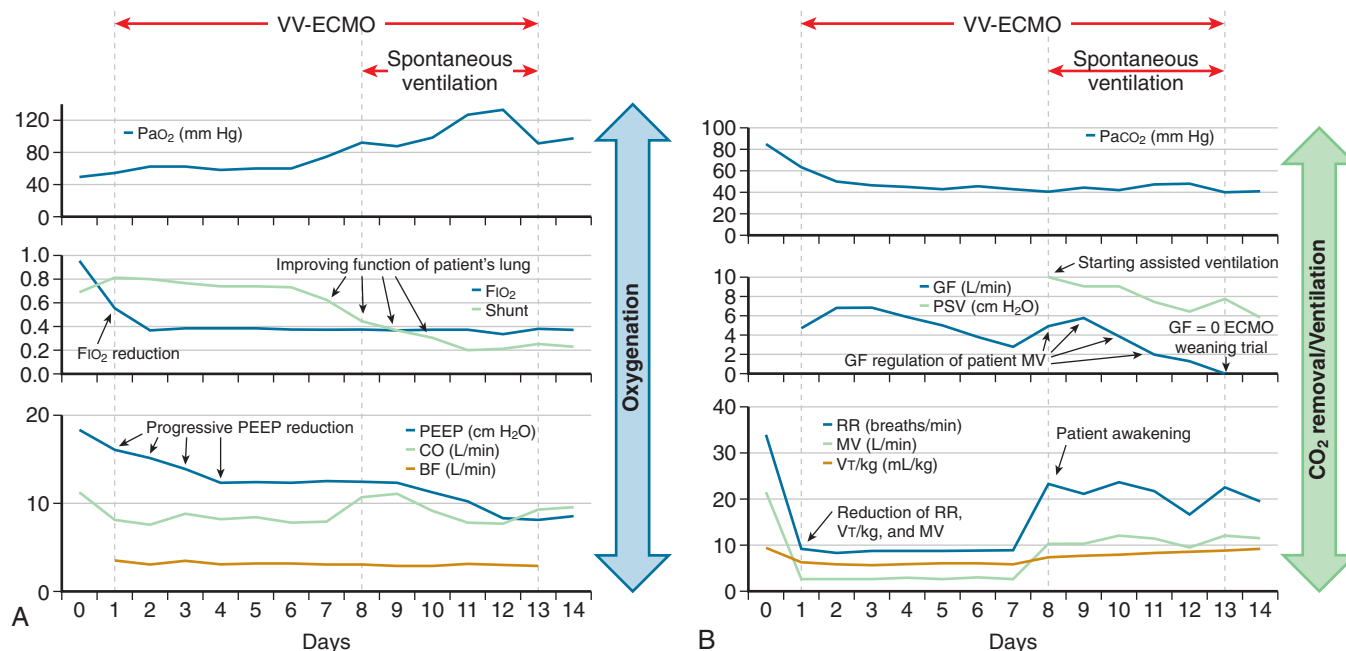

Figure 103-8 Example of ventilatory management in a patient with acute respiratory distress syndrome over 2 weeks. Oxygenation parameters (A) and ventilation parameters (B) are shown, including ventilator and ECMO settings, gas exchange, and hemodynamics day by day. As soon as ECMO starts, respiratory rate (RR), tidal volume ($\text{V}_\text{T}/\text{kg}$), and minute ventilation (MV) are reduced. Positive end-expiratory pressure and FiO_2 are reduced progressively. After the 6th day, intrapulmonary shunt (shunt) starts to decrease and PaO_2 improves. On the 8th day, the patient is awakened. RR, V_T , and mechanical ventilation (MV) are controlled by modulating ECMO sweep gas flow (GF) until the patient is ready to be weaned on the 13th day. Throughout the ECMO treatment, an ECMO blood flow (BF) of around 3 L/min is maintained while the cardiac output ranges between 7 and 10 L/min.

pulmonary artery catheter allows direct measurement of pulmonary arterial pressure, which is important because pulmonary hypertension is common in patients with ARDS treated with ECMO and has negative prognostic implications. A ventilator strategy directed at extreme lung rest is generally associated with worsening pulmonary hypertension, which may necessitate specific treatment (inhaled nitric oxide, sildenafil) to prevent right ventricular failure. It is not unusual that a patient has to be converted from VV-ECMO to VA-ECMO due to development of right ventricular failure.⁵⁴

ANTICOAGULATION AND HEMATOLOGIC MONITORING

Anticoagulation during VV-ECMO is commonly achieved by continuous intravenous heparin infusion, targeted to a *partial thromboplastin time* (aPTT) of 45 to 60 seconds and/or to an *activated clotting time* (ACT) of 1.5 to 2 times normal. The main advantage of ACT is its prompt availability at the bedside. Fibrinogen and antithrombin III should be maintained within the normal ranges.

After starting ECMO, the platelet count usually decreases. Platelet counts should be maintained above 50,000/ μ L in all patients, but a higher threshold of 100,000/ μ L is recommended in the presence of active bleeding.

Activation of the coagulation cascade with subsequent clot formation in the circuit is accompanied by a progressive decrease in platelet counts and fibrinogen levels, and consumption of coagulation factors that may lead to a syndrome similar to disseminated intravascular coagulation. D-dimer levels are a reliable indicator of circuit thrombosis.^{59a} Signs of activation of the coagulation cascade along with decreased performance of the oxygenator and/or increase of trans-membrane pressure should prompt replacement of ECMO circuit.

In the presence of heparin-induced thrombotic thrombocytopenia, the heparin infusion should be discontinued and an alternative anticoagulant such as argatroban should be used.⁶⁰⁻⁶¹

Red cell transfusion policy during ECMO is extremely variable because there is no consensus on the optimal hematocrit level. Available guidelines recommend maintenance of hematocrit within normal limits to minimize blood flow requirements and maximize oxygen delivery of both the membrane lung and native lung.

ECMO COMPLICATIONS

Bleeding complications remain the most frequent and serious complication in ECMO patients. The best sources of information on the incidence of complications are the ELSO registry reports.⁶² Localized bleeding, especially from cannula insertion sites or from surgical sites, are common, reported in approximately 17% and 16% of patients, respectively. Simple compression or packing maneuvers are often sufficient to treat these complications.

Intracranial bleeding is reported in 3.9% of patients and is associated with an overall survival rate of only

17%. Pulmonary and gastrointestinal hemorrhage have been observed in approximately 8% and 5% of patients, respectively.

In the presence of generalized and persistent bleeding, heparin should be reduced or discontinued, and transfusion of fresh frozen plasma and platelets should be considered. To prevent bleeding, it is worthwhile to minimize procedures such as intramuscular or subcutaneous injections, thoracentesis, chest tube insertion, and substitution of nasogastric or urinary catheters.

WEANING FROM VENO-VEIN ECMO

Weaning from ECMO is the progressive reduction of the ECMO contribution to oxygenation and CO₂ removal as the gas exchange capability of the native lung improves and the patient's clinical conditions stabilize (see Fig. 103-8). The decision to disconnect a patient from ECMO is based on the composite assessment of several aspects of the patient's respiratory function (gas exchange function, respiratory mechanics) and hemodynamics. According to the ELSO guidelines, ECMO discontinuation can be considered when 50% to 80% of total gas exchange is supported by the patient's lungs.^{20,22}

Patient readiness for weaning may easily be assessed during VV-ECMO by simply turning off the sweep gas flow. At zero flow, no oxygen is added and no CO₂ is removed from the blood flowing through the ECMO circuit; at this point, the only gas exchange system is the patient's lung. In patients still on controlled mechanical ventilation, during the trial off-ECMO respiratory rate, V_T and F_{IO₂} should be adjusted to values that are considered acceptable without ECMO. Most commonly, ECMO is discontinued when the patient is receiving assisted spontaneous ventilation. After the gas flow is stopped, the patient usually has to increase respiratory effort and minute ventilation, and ventilator support should be adjusted accordingly. When the patient is considered ready, the extracorporeal support can be definitively discontinued and cannulas removed. To remove cannulas placed percutaneously, a purse-string suture, inserted around the cannulation site, is tightened immediately after decannulation and localized pressure is applied for at least 30 minutes.

LOW-FLOW CO₂ REMOVAL: INDICATIONS AND TECHNOLOGY

Following the original concept developed by Kolobow and Gattinoni,^{12,13} several new devices and technical approaches have been recently implemented to perform extracorporeal CO₂ removal. The key is that because these approaches use a lower blood flow, smaller cannulas, and less anticoagulation, they have fewer side effects. The direct consequence of removing CO₂ through these devices is that it is possible to reduce the minute ventilation required through the native lung. Therefore, any clinical situation in which such a reduction may be beneficial represents a potential indication for extracorporeal CO₂ removal. These include clinical

situations in which the goal is to (1) decrease V_T and RR in ARDS patients for “ultraprotective ventilation,” (2) decrease dynamic hyperinflation and facilitate weaning in patients with exacerbations of *chronic obstructive pulmonary disease* (COPD) or severe asthma, or (3) avoid intubation or speed extubation of immunocompromised patients.

Depending on the range of operative blood flows and bypass configuration, the available techniques may be classified as follows:

1. *Low-flow $EC_{CO_2}R$ (LF- $EC_{CO_2}R$)*. Various devices are available that operate with low extracorporeal BF, ranging from 250 to 500 mL/min. Depending on the level of CO_2 content in the venous blood, these systems allow removal of up to about 80 to 100 mL of CO_2 /min (see Fig. 103-7). Most of these systems can be employed with small (14- to 17-French), double-lumen catheters similar to those used for continuous renal replacement techniques. Livigni and colleagues⁶³ were the first to describe one of these devices (Decap, Hemodec, Salerno, Italy) in 2006. A nonocclusive roller pump was used to drive the blood through an oxygenator at 300 mL/min; the device also included a hemofilter in series with the oxygenator to allow recirculation of plasma water in order to dilute the blood entering the oxygenator and prevent blood clotting. Since then, a number of similar devices have been described. The main limitation of these devices is the need for frequent circuit substitutions (every 24 to 48 hours). Recently, this problem has been partially solved by avoiding the use of the hemofilter and using polymethylpentene oxygenators instead of the less expensive polypropylene ones. A different device is the Hemolung (Hemolung, Alung Technologies), in which the membrane lung and the centrifugal pump are combined together, acting as one unit. The pump rotor (impeller) transmits a rotational motion to the blood increasing gas exchange efficiency.^{64,65} Compared with other low-flow systems, the Hemolung shows longer duration and slightly higher CO_2 removal performance.⁶⁶
2. *Arteriovenous CO_2 removal ($AV_{CO_2}R$)*. This AV-ECMO system uses a simplified, high-technology membrane lung (Novalung), characterized by an extremely low resistance to blood flow, high gas transfer efficiency, and absence of a heat exchanger. The Novalung device is applied to an arteriovenous shunt obtained by connecting the femoral artery to the femoral vein using two cannulas inserted percutaneously. According to the mean systemic arterial pressure and to the size of the arterial catheter (15- or 17-French), an extracorporeal BF up to 2.5 L/min can be achieved.⁶⁶ Main limitations of this system are the dependency on the patient's hemodynamic status and the risk of ischemia of the leg distal to the arterial cannulation site. Close monitoring of foot temperature and pulse oximetry is recommended; if signs of ischemia are noted, prompt action is required to prevent permanent damage to the lower limb.
3. *VV- $EC_{CO_2}R$* . Classical $EC_{CO_2}R$ techniques as proposed by Gattinoni and Kolobow use standard adult ECMO systems at a blood flow of 1.5 to 2.5 L/min. By mounting low-medium surface oxygenators such as pediatric or small adult oxygenators on small-size tubes and cannulas, different ranges of flow can be achieved (from

500 mL/min up to 2 to 2.5 L/min), allowing removal of up to 100% of the entire metabolic CO_2 production. For example, a standard pediatric ECMO system with small single- or double-lumen cannulas may be used in adult patients for most CO_2 removal indications. The latest device to enter the arena of CO_2 removal was the *Pump Assist Lung Protection* (PALP, Maquet, Germany). It consists of a small size centrifugal pump and a pediatric-size polymethylpentene oxygenator with no heat exchanger. According to the cannula size, the PALP allows BF from 500 mL/min up to 2.5 L/min and a wide range of CO_2 removal.

CO₂ REMOVAL FOR ULTRAPROTECTIVE VENTILATION IN ARDS

The idea of ultraprotective ventilation originates from the observation that, despite the use of a “protective” V_T , a substantial amount of lung³¹ can still be hyperinflated and hence a further reduction of V_T may be beneficial. Moreover, a direct consequence of the application of protective ventilatory settings is often the necessity of accepting not only lower levels of oxygenation but also a certain degree of respiratory acidosis (permissive hypercapnia). As such, extracorporeal CO_2 removal represents a powerful technique to ensure protective ventilation and prevent VILI, while maintaining adequate gas exchange in patients in whom oxygenation is not a major issue. In 2006, Bein and colleagues⁶⁷ published an important report about the clinical application of $AV_{CO_2}R$ in 90 ARDS patients with severe, unresponsive respiratory failure. With $AV_{CO_2}R$, they were able to reduce ventilation to less injurious settings while oxygenation, by whatever mechanism, was improved. In 22% of the cases, major complications were observed, the most common being ischemia of the leg distal to arterial cannulation. $AV_{CO_2}R$ has also been employed in patients with severe influenza A (H1N1). In these patients, the pumpless bypass allowed reduction of P_{aCO_2} levels, improvement in pH, and more protective mechanical ventilation.⁶⁸

In a recent application of $AV_{CO_2}R$, Bein and colleagues⁶⁸ investigated the effect of an ultraprotective ventilatory strategy on the number of ventilator-free days in ARDS patients. Seventy-nine patients randomly received ultraprotective ventilation with V_T of 3 mL/kg while on $AV_{CO_2}R$ or a conventional protective ventilatory strategy with V_T of 6 mL/kg. The study was underpowered and failed to show significant benefits in the 3 mL/kg group. However, a post hoc analysis showed a significant improvement in ventilator-free days at 60 days in the subgroup of patients who had more severe hypoxemia ($P_{aO_2}/F_{iO_2} < 150$) at baseline.⁶⁹

Terragni and colleagues⁷⁰ were the first to employ a LF- $EC_{CO_2}R$ device (the Decap device) in ARDS patients. They were able to decrease V_T from 6 to 4 mL/kg while keeping constant CO_2 and pH levels in a group of ARDS patients at risk of VILI (P_{plat} higher than 28 cm H_2O). They also showed a reduction of circulating inflammatory cytokines and a reduction of lung hyperinflation.

In summary, the available literature demonstrates that the use of very low V_T combined with some form of extracorporeal CO_2 removal is feasible without major side effects. However, future studies are required to demonstrate the potential survival benefits from the use of ultraprotective ventilatory strategies in ARDS patients.

CO₂ REMOVAL FOR COPD

COPD is the fourth leading cause of death in western countries and is a major cause of morbidity worldwide.⁷¹ COPD patients experience recurrent episodes of hypercapnic respiratory failure (acute exacerbation) that are associated with poor prognosis and increased mortality.⁷² Most patients are successfully managed with *noninvasive positive pressure ventilation* (NIPPV), which represents the standard first-line treatment in acute exacerbations of COPD.⁷³ However, intubation and invasive mechanical ventilation are still required in 26% to 54% of patients.^{74,75} In these patients, invasive mechanical ventilation is associated with a high rate of complications (ventilator-associated pneumonia, barotrauma, hemodynamic compromise and failure to wean), which ultimately increases morbidity and mortality.¹⁹ The main cause of NIPPV failure is the imbalance between the reduced capacity of the respiratory muscles to generate pressure and the respiratory load, which is increased as a result of the high ventilatory needs and expiratory flow limitation. The rationale for the use of CO_2 removal techniques is to decrease minute ventilation and consequently airflow limitation and respiratory effort while decreasing CaO_2 and increasing pH. ECCO_2R may play a role at different stages of COPD exacerbations: to avoid intubation during the NIPPV phase and to reduce the duration of invasive mechanically ventilation and facilitate weaning.

Surprisingly, the use of ECCO_2R in acute COPD patients has not been investigated until recently. Cardenas and colleagues⁷⁶ recently applied a low-flow extracorporeal system in a difficult-to-wean COPD patient; extracorporeal removal of CO_2 allowed a 30% decrease of minute ventilation with concomitant reduction in hyperinflation and improvement in gas exchange. Garcia and colleagues⁷⁷ applied VV- ECCO_2R in 10 COPD patients during weaning from mechanical ventilation or as a bridge to lung transplant. The range of blood flows was 1.6 to 4.9 L/min while the range of $\dot{V}\text{CO}_2$ of the membrane lung was 54 to 570 mL/min. Six patients were successful weaned or underwent transplantation.

The only available report on the use of LF- ECCO_2R techniques was published by Burki and colleagues,⁷⁷ who employed the Hemolung device in a mixed population of COPD patients: 7 patients undergoing NIPPV at high risk of intubation (group 1), 2 patients not weanable from invasive mechanical ventilation (group 2), and 11 patients on invasive mechanical ventilation who had already experienced unsuccessful weaning attempts (group 3). The average blood flow and $\dot{V}\text{CO}_2$ of the membrane lung were 430 ± 74 mL/min and 83 ± 16 mL/min, respectively. The average duration of LF- ECCO_2R treatment was 104 ± 59 hours. All patients in group 1 and 2 and three patients in group 3 were successfully treated.

CO₂ REMOVAL AS BRIDGE TO TRANSPLANT (see Chapter 106)

Several reports have described the use of ECMO as a bridge to lung transplant.⁷⁸⁻⁸⁰ Most commonly, standard ECMO or AVCO_2R has been employed. Fisher and colleagues⁷⁹ reported the use of AVCO_2R in 12 patients suffering from severe ventilation-refractory hypercapnia and respiratory acidosis, with high urgency for lung transplantation. The length of extracorporeal support was 15 ± 8 days; 10 patients were successfully bridged to lung transplant. The only report on the use of LF- ECCO_2R as a bridge to transplant is that of Ricci and colleagues,⁸¹ who applied AVCO_2R in 6 patients and LF- ECCO_2R in another 6 patients. Mean length of extracorporeal support was 13.5 ± 14.2 days, with no differences between the two devices. Finally, a novel and interesting application of ECMO as a bridge to lung transplantation is in patients who are awake and spontaneously breathing. Fuehner and colleagues⁸² reported the results of a retrospective analysis comparing 26 nonintubated patients receiving ECMO as a bridge to lung transplantation with a historical control group of patients treated with conventional mechanical ventilation. Duration of ECMO support or MV was comparable in both groups. Patients in the awake ECMO group were able to eat, drink, and talk. Nineteen of 26 patients in the awake ECMO group were managed without need for intubation.

The possibility of managing patients with acute respiratory failure using ECMO, while avoiding intubation, is exciting. A group of patients for whom awake ECMO may be promising are hematologic and immunocompromised patients.

Key Points

- *Extracorporeal membrane oxygenation* (ECMO) refers to a technique of life support that consists of diverting part of the patient's blood through an artificial lung for gas exchange (oxygenation and CO_2 removal) and then returning it to the patient.
- The primary indications for *veno-venous ECMO* (VV-ECMO) are hypoxemic respiratory failure in patients with a high risk of mortality (patients with $\text{PaO}_2/\text{FiO}_2 < 80$ mm Hg with $\text{FiO}_2 > 90\%$ and Murray score of 3 to 4), and reduction of tidal volume and plateau airway pressure in ARDS patients at high risk of ventilator-induced lung injury. Contraindications to ECMO include advanced age, severe disability, and incurable malignancy.
- Mortality during VV-ECMO correlates with a greater number of days of mechanical ventilation before ECMO institution. ECMO treatment should be established before lung injury has become irreversible.
- The efficiency in removing CO_2 is significantly higher than that of adding oxygen. Depending on the blood flow, the technique may be used mainly for CO_2 removal (ECMO blood flow < 2 L/min) or for both CO_2 removal and oxygenation (ECMO blood flow up to 5 to 6 L/min).

- With ECMO, blood flow is the main determinant of patient oxygenation. Blood flow should be set to the lowest level that provides adequate oxygenation. ECMO sweep gas flow is the main determinant of CO₂ removal and, consequently, determines the minute ventilation needed for the native lung.
- During VV-ECMO, the native lung is managed to prevent VILI. Respiratory rate, tidal volume, plateau airway pressure, and FiO₂ are generally decreased as much as possible while maintaining arterial oxygenation.
- Anticoagulation during VV-ECMO is commonly achieved by continuous intravenous heparin infusion, targeted to a partial thromboplastin time of 45 to 60 seconds and/or to an activated clotting time of 1.5 × normal values. Bleeding complications remain the most frequent complication in ECMO patients. Intracranial bleeding is reported in 3.9% of patients and is associated with an overall survival rate of only 17%.
- The main indications for CO₂ removal are to decrease the tidal volume and respiratory rate in ARDS patients for “ultraprotective ventilation,” decrease dynamic hyperinflation and facilitate weaning in patients with exacerbations of COPD or severe asthma, and avoid intubation or speed extubation of immunocompromised patients.

WITHHOLDING AND WITHDRAWAL OF LIFE-SUSTAINING THERAPY

What Therapies Are Withheld and Withdrawn

Withholding and Withdrawal of Intubation and Mechanical Ventilation

INTRODUCTION

Patients with acute, chronic, and acute-on-chronic respiratory failure often suffer from symptoms such as pain and dyspnea and have a high expected mortality rate. These patients may be aggressively treated when they, their families, and their physicians believe that doing so is reasonable and consistent with the patient's treatment preferences. Alternatively, therapies such as mechanical ventilation, which can often reverse respiratory failure in patients with acute decompensation, may be forgone for patients who refuse such treatments and for those whom a trial of intensive treatment fails to achieve the patient's medical goals. When clinically appropriate, the withholding and withdrawal of life-sustaining therapy is supported by ethical and legal principles. These principles, along with the process of medical decision making and the desirable components of end-of-life care, are discussed in detail in this chapter.

PREDICTING THE OUTCOME OF RESPIRATORY FAILURE

The prevalence of diseases that cause respiratory failure, coupled with the morbidity and mortality they cause, has prompted clinicians and investigators alike to seek prognostic information about patients with these disorders. Some of this prognostic information has been derived from single- or multi-institutional studies of specific conditions such as *chronic obstructive pulmonary disease* (COPD),¹ *Pneumocystis jirovecii* pneumonia in patients with the *acquired immunodeficiency syndrome* (AIDS),² and *acute respiratory distress syndrome* (ARDS).³ Other information has come from studies of

patients in certain age groups, such as the elderly,⁴ or from studies of interventions, such as mechanical ventilation.⁵ These studies in turn have been used to develop tools to predict not only patient outcome but also the need for admission to the *intensive care unit* (ICU) for diseases such as pneumonia.⁶

Additional information has been obtained from the use of prognostic scoring systems based largely on physiologic variables such as arterial PCO₂ and PO₂ recorded on hospital admission or at other times. Although many of these systems were developed specifically for patients in ICUs, where physiologic variables are routinely measured, they also have been applied to patients elsewhere. Perhaps the best known prognostic scoring system is the *Acute Physiology and Chronic Health Evaluation* (APACHE), which has gone through four iterations.⁷⁻¹⁰ Similar to APACHE, another prognostic system developed for the *Study to Understand Prognosis and Preferences for Outcomes and Risks of Treatment* (SUPPORT) was based on patient diagnosis, age, number of days in the hospital before study entry, presence of cancer, neurologic function, and 11 physiologic variables recorded on day 3 of study entry.¹¹

Prognosis based on the experience of individual clinicians or institutions is necessarily limited; despite wide use, such prognostication has never been subjected to rigorous evaluation. Although prognostication based on broader investigations of specific diseases should be more accurate, the changing outcome from *P. jirovecii* pneumonia,¹² ARDS,¹³ and other conditions over time limits the use of these investigations in predicting outcome unless they are frequently updated. Furthermore, the tools based on these studies that may be used to determine the need for intensive care for pneumonia and other diseases have limited predictive value, presumably in part because the outcome from these conditions has changed over time.

Physiologically based prognostic scoring systems have been shown to be as accurate—or inaccurate—as clinical assessment by physicians and nurses.¹⁴ They have demonstrated good calibration in that the overall hospital mortality predicted by the systems is comparable with that actually observed in research studies. Nevertheless, the systems have not discriminated well between individual survivors and nonsurvivors. For example, recommended prediction criteria were not effective in identifying a SUPPORT population with a survival prognosis of 6 months or less, limiting their use in determining which patients might generally meet hospice eligibility requirements.¹⁵ Furthermore, the system is poor at predicting imminent death; when the SUPPORT prognostic system was used to derive the likelihood of survival for patients on the day before their actual death, the median predicted likelihood of survival for 2 months was 17% and, when derived 1 week before actual death, the predicted likelihood was 51%.¹⁶

Overall, prognostic scoring systems have contributed greatly to our understanding of the general outcomes of patients with respiratory failure and other conditions. Furthermore, the calibration and discriminatory power of the systems may improve as more studies of the systems are performed and more patients are entered into their databases. Yet, at present, the systems are imperfect in predicting outcome in an individual patient. For the foreseeable future, therefore, the use of prognostic scoring systems should continue to be adjunctive in that they provide information to help in medical decision making but cannot be used by themselves to decide who is destined to die despite intensive care.

TREATMENT GOALS AT THE END OF LIFE

The limitations of prognostication are unfortunate because patients' and their families' predictions of prognosis largely determine their treatment preferences, just as physicians often base their recommendations to patients and families on their own prognostic estimates. For example, many patients with acute respiratory failure due to potentially reversible causes, as well as their families, generally prefer goals focused on rescue and life prolongation until death appears highly likely.¹⁷ In contrast, patients with end-stage chronic lung diseases such as COPD and lung cancer often prefer care that is focused on maintaining comfort rather than on extending their lives.¹⁸ These preferences appear to be related to patients' perceptions of how far advanced their underlying conditions are. For example, hospitalized patients with lung cancer who thought they were going to live at least 6 months were more likely to favor life-sustaining treatment over comfort care than patients who thought they had at least a 10% chance of dying within the next 6 months.¹⁹ Of course, the treatment goals of life prolongation and maintenance of comfort need not be mutually exclusive. Life support and symptom relief are often sought simultaneously.

The term *end-of-life care* is meant to encompass two processes. One, the withholding and withdrawal of life support represents the tapering of life-sustaining interventions

such as pulmonary rehabilitation in the outpatient setting and mechanical ventilation in the ICU.²⁰⁻²³ The other, the administration of palliative treatment, applies, among other things, to improving patient comfort by giving sedatives and analgesics. Combining these two processes signifies that end-of-life care involves more than removing something—in this case, life-saving treatments—from patients. It also means giving something to them: proper medical decision making; thoughtful communication; an appreciation of their needs and those of their families, physicians, and other caregivers; the use of an appropriate setting for death; and the management of pain, dyspnea, and other symptoms. This comprehensive and compassionate approach is what is meant by the expression “intensive caring at the end of life.”²⁴

WHERE AND HOW PATIENTS DIE

In less developed countries, most patients with respiratory failure who die do so at home largely because they have limited access to hospitals and other institutional settings. In the United States and other developed nations, however, patients most often die outside the home. For example, of the large cohort of hospitalized patients in SUPPORT, 47% died within 6 months of study enrollment and 55% of these died during the enrollment hospitalization. Of the patients who survived the enrollment hospitalization, 46% died during hospitalization later that year and only a minority died in a nursing home or hospice, let alone at home.²⁵ Similarly, in one investigation of all the deaths recorded in six states during 1999, 38% of patients died in hospitals and 22% died following ICU admission.²⁶ Using these data to project national estimates, the investigators concluded that 540,000—fully one fifth—of all patients who die in the United States do so in ICUs each year.²⁷

Many factors account for the high prevalence of in-hospital and in-ICU deaths in the United States and, presumably, other developed countries. Among them are the availability of these facilities and of the physicians who admit patients to them and the fact that fewer elderly persons still reside with their families. In the United States, patients must be determined to have less than 6 months to live to qualify for hospice placement, but it is difficult to predict with accuracy which patients have such a limited life expectancy. Most patients want to live as long as possible unless life is a burden to them and their families, and many physicians will try to forestall death unless there is a high degree of certainty that patients will be left with unacceptably burdensome functional impairment.

When ICUs were first developed during the 1950s and 1960s in the United States and Europe, patients who died in them did so despite full support, including attempted *cardiopulmonary resuscitation* (CPR). The wishes of patients and their surrogates regarding such support rarely were solicited, and *do-not-attempt-resuscitation* (DNAR) orders were rarely written for the patients because most hospitals felt obligated to perform CPR on everyone. Indeed, a host of potentially restorative treatments were automatically provided with little concern about their effectiveness or desirability. This approach was based on the belief, held by both health professionals and the public, that technologies

should be used to preserve life whenever possible regardless of the human and economic costs.²⁸

In recent years, however, the “technologic imperative” has been challenged, just as the expenses of the ICU have been scrutinized.²⁹ CPR has been shown often to be ineffective in certain hospitalized patients.³⁰ Patients have been found not to prefer attempted restorative therapy in all instances, and courts in the United States have declared that these patients have a “right to die.”³¹ The ethical, legal, and economic consensus that has resulted from these developments has been reflected in a series of statements from professional societies^{32–37} on the appropriateness of forgoing life-sustaining therapies at the end of life. As a result, although hospitalized patients once died despite attempted restorative treatment, today they are more likely to die during the withholding and withdrawal of life support and the administration of palliative care, especially in the ICU.^{22,23}

ETHICAL AND LEGAL JUSTIFICATION FOR END-OF-LIFE CARE

JUSTIFICATION FOR WITHHOLDING AND WITHDRAWING LIFE-SUSTAINING THERAPY

The withholding and withdrawal of life support is justified by four ethical principles³⁸ (Table 104-1). The first principle is *beneficence*: the physicians’ obligation to do good for patients. Relieving pain and suffering, rather than sustaining life at all costs, may be beneficent in certain situations. The second principle is *nonmaleficence*: the physicians’ obligation to avoid harm. Life-sustaining interventions may be

painful and unlikely to sustain life in a way judged meaningful by the patient, and foregoing such interventions may reduce harm. The third principle is *autonomy*: respect for the patients’ right of self-determination. Patient autonomy is reinforced when patients are allowed to refuse unwanted life-sustaining therapies. The fourth principle is *justice*: the fair allocation of medical resources. Justice may be served if life support is withdrawn from one patient with a poor prognosis to help another patient with a better prognosis, such as during a mass casualty event or in an influenza pandemic.³⁹

In the United States, the withholding and withdrawal of life-sustaining therapies is justified legally by the principles of informed consent and refusal, which have strong roots in common law.⁴⁰ The right of adults who are capable of making medical decisions either to consent to or to refuse treatment was first established in *Schloendorff v. Society of New York Hospitals* in 1914.⁴¹ In this case, the New York Court of Appeals declared: “Every being of adult years and sound mind has the right to determine what should be done with his own body; and a surgeon who performs an operation without his patient’s consent commits an assault, for which he is liable in damages, except in cases of emergency when the patient is unconscious or when it is necessary to operate before consent can be obtained.”

The right of adults with decision-making capacity to refuse treatment was advanced in cases such as *Bartling v. Superior Court*⁴² and *Bouvia v. Superior Court*⁴³ in California. In the first of these cases, the Court of Appeals allowed a man with advanced COPD to have a mechanical ventilator removed against the wishes of his physicians and of the hospital. In the second, the appeals court ordered a hospital to stop force-feeding a quadriplegic woman against her will even though she might die in the process. Most states have dealt with similar cases, and the principle that adults with capacity can refuse unwanted therapies is now widely accepted.

The U.S. Congress supported the importance of respect for patient autonomy by passing the Patient Self-Determination Act. This statute mandates that patients admitted to medical facilities be asked whether they have advance directives and, if they do not already have them, that they be assisted in drawing up directives.⁴⁴ Advance directives are of two types: instructional directives that state what patients want done in a given situation (e.g., living wills) and proxy directives that appoint surrogates to make decisions for them in these situations (e.g., the durable power of attorney for health care). Although there are well-documented shortcomings,⁴⁵ advance directives have the potential for extending patient autonomy beyond the point of incapacity, even though this potential has not been fully realized.⁴⁶

Because of their illness and sedation, many critically ill patients cannot partake in the medical decision-making process. In this circumstance, family members and other surrogates, if available, may consent to or refuse treatment for them. Parents have a long-standing right, indeed an obligation, to speak for their dependent children. The legal right of surrogates to act for incapacitated adult patients was established in *In re Quinlan*⁴⁷ in which the Supreme Court of New Jersey allowed the parents of a vegetative patient to refuse mechanical ventilation for their daughter

ETHICAL PRINCIPLES

Beneficence
Nonmaleficence
Autonomy
Justice

LEGAL PRINCIPLES: RIGHT OF INFORMED CONSENT AND REFUSAL

Exercised by patients with decision-making capacity
Exercised by family members for incapacitated patients
 As authorized under proxy directives
 Using a substituted-judgment standard (facilitated by instructional directives)
 Using a best-interests standard
Exercised by a court-appointed conservator
 Using a substituted-judgment standard (facilitated by instructional directives)
 Using a best-interests standard
Exercised by physicians, often after ethics committee review
 Using a substituted-judgment standard (facilitated by instructional directives) (legal justification in a few states)
 Using a best-interests standard (no legal justification)

From Beauchamp TL, Childress JF, editors: Principles of biomedical ethics, ed 4. Oxford, 1994, Oxford University Press; and Luce JM, Alpers A: End-of-life care: what do the American courts say? *Crit Care Med* 29:N40–N45, 2001.

through the mechanism of surrogate decision making. Through this mechanism, family members also were allowed to make life-determining decisions for their adult relative in *Barber v. Superior Court*⁴⁸ in California. In this case, the court determined that not only mechanical ventilation but also nutrition and hydration—indeed, any therapy that was not clearly benefiting the patient—could be forgone.

The U.S. Supreme Court dealt with the issue of surrogate decision making in the case of *Cruzan v. Director, Missouri Department of Health*.⁴⁹ In this case, a family argued that it was unconstitutional for a chronic care facility in Missouri to deny their request to remove a feeding tube from their vegetative adult daughter. The facility argued that the daughter had not specified her wishes not to be fed artificially in advance of incapacity. In its *Cruzan* decision, the Supreme Court allowed Missouri and other states to require “clear and convincing evidence” of patients’ prior wishes before care was forgone for them. Nevertheless, it did not demand this requirement of other states, and it accepted the argument that the right of adult patients with decision-making capacity to refuse any and all therapies was protected under the Constitution.

Substituted judgment, through which surrogates make inferences about what treatment decisions patients *would* make if they were able to make decisions for themselves, is the highest standard under which surrogates may make medical decisions for incapacitated patients. Nevertheless, surrogates also may consider the patients’ best interests. One delineation of a best-interests standard is that of the New Jersey Supreme Court relative to *In re Conroy*.⁵⁰ In this case, a nephew asked that a feeding tube be withdrawn from his elderly aunt, who had not declared her wishes before becoming demented, on the grounds that forgoing nutrition and hydration was in her best interest. The court would allow the best-interests standard in this case only because the burdens of continuing the patient’s life outweighed the benefits and because the recurring, unavoidable pain of life with treatment was such that administering therapies such as nutrition and hydration was inhumane. These requirements were imposed because the court considered the best-interest standard less compelling than the substituted-judgment standard.

Another legal perspective on the standards of substituted judgment and best interests came in the case of *Wendland v. Wendland*.⁵¹ This case involved a middle-aged man who was conscious but hemiplegic, uncommunicative, and unable to feed himself after a motor vehicle accident. After his feeding tube repeatedly became dislodged, his wife, who was his conservator, refused to authorize its reinsertion. In support of her decision, she cited her husband’s statements before his accident that he would not want to live in a severely debilitated condition. At this point, his mother went to court to block the plan not to reinsert the feeding tube, and it was reinserted. Mr. Wendland subsequently died, but the California Supreme Court deliberated on the issue of whether a conservator could withhold or withdraw life support from a patient who was conscious but incapable of articulating his current wishes. The Court ultimately ruled that feedings could be discontinued only if there was clear and convincing evidence that “the patient wished to

refuse life-sustaining treatment or that to withhold such treatment would have been in his best interest,” which was not thought to be true of Mr. Wendland. The decision in this case suggests that the courts are unlikely to allow surrogates to limit treatment in patients who are neither terminally ill nor permanently unconscious unless the patients have specified what they would want done in such a situation.⁵²

Legal guidelines are less clear when incapacitated patients lack family members or other surrogates. Some states (e.g., Hawaii, Connecticut) allow physicians to make decisions for such patients on the basis of wishes expressed to the physicians when the patients had decision-making capacity. However, no state explicitly allows physicians to make decisions on the basis of a best-interests standard. Be that as it may, as shown in a study from seven U.S. medical centers, some physicians do make decisions to withhold or withdraw life-sustaining therapy from incapacitated patients on the basis of best interests, usually after consultation with their colleagues or with a hospital ethics committee.⁵³ Other physicians ask the probate court to appoint conservators or other advocates for the patients, presumably to ensure a fair, transparent, and deliberate process of decision making for these vulnerable patients.

Before leaving the subject of justification for withholding and withdrawing life support, it is important to mention that decisions regarding this process are different for brain-dead patients than they are in patients who have lesser degrees of neurologic impairment. In the United States, death is defined as the total and irreversible loss of either cardiopulmonary function or the function of the entire brain.⁵⁴ The determination of death by whole-brain criteria requires the demonstration of coma, indicating the loss of cerebral hemispheric function, and the documentation of absent corneal, oculovestibular, and ventilatory reflexes, indicating loss of function of the brain stem. Absence of ventilatory reflexes is demonstrated by an abnormal apnea test in which intubated, nonparalyzed patients removed from mechanical ventilation and given oxygen fail to initiate respiratory muscle efforts despite an increase of their arterial PCO₂ to at least 60 mm Hg.

Life-sustaining therapy usually can be forgone without a formal declaration of brain death. Conversely, some surrogates may insist that therapy be continued until patients die, in which case determining death by whole-brain criteria may be desirable. That said, the only patients in whom brain death must be determined are those who seem to be dead and whose organs will be transplanted after life support is withheld or withdrawn. Regarding the latter patients, one might argue that withdrawing life support from someone who is dead is an oxymoron. Because of this argument, and because brain-dead patients usually receive mechanical ventilation and other interventions only until their organs can be harvested, “life support” for them can be likened to “organ support.”

The ethical and legal justification for removing therapies from brain-dead patients is not just that the therapies generally are unwanted by patients and surrogates in this situation but also that the patients are dead and cannot benefit from them. Inasmuch as the patients are dead, physicians have no obligation to treat them, and they do not need to

obtain consent from surrogates before withholding or withdrawing treatment. Nevertheless, consent is required for organ retrieval and transplantation. Furthermore, the families of brain-dead patients frequently do not understand the concept of brain death and consider the patients to be alive because their chests rise and fall as the ventilator cycles and a tracing of their cardiac rhythms is displayed on the bedside monitor. Families also may reject the concept of brain death for religious reasons.

Motivated by consideration for such families and by a desire to gain their consent for organ donation, many physicians are appropriately nonconfrontational in addressing the issue of brain death. They take time to explain what death means in a biologic and legal sense, how brain death is determined, and how valuable transplantation can be for organ recipients, as well as for the families of patients who serve as organ donors and even for the patients themselves. This approach is generally helpful to families, regardless of whether they ultimately approve transplantation. It is also useful in maintaining emotional equilibrium during a difficult time for all parties in the ICU.⁵⁵

MEDICAL FUTILITY

Although the ethical principle of autonomy and the legal principles of informed consent and refusal are the most compelling justifications for withholding and withdrawing life support, the concept of futility has also been used as a justification. This concept is invoked on the relatively rare occasions when patients or their surrogates request interventions (particularly those that are costly, scarce, or both) that physicians object to because they believe the patients cannot benefit from them. Some treatments, such as brain transplantation for brain-dead patients, are physiologically futile in that they cannot be accomplished. Other treatments, such as the use of mechanical ventilation in a permanently comatose or brain-dead patient, can succeed physiologically, but some physicians may consider them inappropriate because they cannot result in an outcome that the clinician judges to be valuable.

One group of investigators⁵⁶ sought to define medical futility as an intervention that has been useless in the last 100 cases or that “merely preserves unconsciousness and cannot end dependence on intensive medical care.” In a similar vein, the American Thoracic Society³³ argued that “a life-sustaining intervention may be withheld or withdrawn from a patient without the consent of the patient or surrogate if the intervention is judged to be futile. A life-sustaining intervention is futile if reasoning and experience indicate that the intervention would be highly unlikely to result in a meaningful survival for that patient. Here, meaningful survival specifically refers to a quality or duration of survival that would have value to that patient as an individual. Survival in a state with permanent lack of consciousness (i.e., completely lacking cognitive and sentient capacity) may be generally regarded as having no value for such a patient.”

Despite what has been called the “futility movement,” a broad concept of futility has never achieved consensus within the medical community in the United States or elsewhere, and the American Thoracic Society position has not

gained broad support.⁵⁷ A contrary position has been advanced by the Society of Critical Care Medicine,⁵⁸ which holds that “treatments should be defined as futile only when they will not accomplish their intended goal. Treatments that are extremely unlikely to be beneficial, are extremely costly, or are of uncertain benefit may be considered inappropriate and hence inadvisable but should not be labeled futile. Futile treatments constitute a small fraction of medical care. Thus, employing the concept of futile care in medical decision making will not primarily contribute to a reduction in resource use.”

In some ways, the development of prognostic scoring systems can be seen as an attempt to predict which patients cannot benefit from therapies, especially those that are expensive, and thereby provide a rationale for denying such therapies to them.⁵⁹ Yet most patients and families are quite willing to forgo such therapies even when physicians are not, as indicated by SUPPORT.⁶⁰ Furthermore, a study of the theoretical implementation of a strict futility guideline for more than 4000 SUPPORT patients demonstrated that only minimal cost savings could be realized by not treating patients who were predicted to have a 1% or less 2-month survival.⁶¹ Nearly 75% of the savings in hospital days would have resulted from stopping treatment for 12 patients, one half of whom were younger than 51 years of age and 1 of whom lived 10 months when treatment was continued.

The emphasis on cost savings in the aforementioned study speaks to the fact that arguments about futility often have economic overtones. At one time, it appeared that American society could transition from a “rule of rescue,” in which large sums of money were spent on therapies providing only marginal benefit, to a “rule of reason,” in which this money could be used for primary and preventive care.⁶² Arguments based on futility seem to provide a rationale for forgoing treatment on the grounds that it is not worthwhile, apart from the matter of cost. Yet these arguments conceal value-laden assumptions, and they obscure the underlying issue of rationing.⁶³

Thus, the greatest problem with medical futility is not how it is defined but who defines it.⁶⁴ In this regard, the debate over futility pits physicians, who believe that their training and experience enable them to know what therapies are truly useful and cost-effective, against patients and families, who may feel entitled to such therapies regardless of whether they pay for them directly. Physicians certainly are able to identify physiologic futility, and they are not legally or ethically required to perform procedures they consider nonbeneficial and below professional standards. Benefit, however, seems often to be in the eyes of the beholder: although physicians may regard mere prolongation of life as undesirable in certain circumstances, patients and families may consider it valuable. When these persons want treatments that physicians consider futile in more than a physiologic sense, which party should decide?

The American Medical Association Council on Ethical and Judicial Affairs has stated that, “Since definitions of futile care are value laden, universal consensus on futile care is unlikely to be achieved.”⁶⁵ At the same time, the Council has recommended a process-based approach to futility determinations whereby patients or families who

insisted on therapies that physicians considered futile would be required to undergo a dispute resolution process. Central to this process would be mediation by a hospital ethics committee. If resolution was not reached through mediation, the patients would be transferred to another institution or care would be terminated if transfer were impossible. So-called futility policies based on this model have been developed in Houston, Texas, and other cities.⁶⁶

Based on the Houston experience, the State of Texas adopted a law providing an extrajudicial due process mechanism for resolving medical futility disputes. A survey⁶⁷ of Texas hospitals' experience with this law indicates that a minority of the hospitals had used the due process mechanism and that life-sustaining treatment was discontinued against patients' or surrogates' wishes in only a small number of cases. Furthermore, the constitutionality of the Texas statute has not been determined at the appellate or U.S. Supreme Court level. As a result, the implications of the Texas statute for that state and for the rest of the United States are unclear.

To date, legal cases such as *In re Helen Wanglie*⁶⁸ and *In the Matter of Baby K*⁶⁹ suggest that judges are unwilling to allow physicians to withhold or withdraw support from patients when the physicians ask to do so and the patients or families object. In the first of these cases, a court in Minneapolis refused to replace a husband who was seeking continued life support for his wife, life support which her physicians considered nonbeneficial, with another conservator who might allow support to be forgone. In the second, a Virginia court required that physicians repeatedly resuscitate an anencephalic infant at the request of its mother but against their own wishes, reasoning that to do otherwise would violate the Emergency Medical Treatment and Active Labor Act.

In contrast, the case of *Gilgunn v. Massachusetts General Hospital*⁷⁰ indicates that physicians are likely to obtain legal results more to their liking when they refuse to provide treatment they consider futile and defend their decisions in court as consistent with professional standards. In this case, a jury in Boston exonerated physicians at Massachusetts General Hospital for removing a patient from life support and writing a DNAR order for her over the objections of her daughter. The patient's husband and other children did not protest the physicians' actions, and the jury apparently believed that the physicians acted within the standard of care. This case does not set legal precedent because a written judgment was not rendered. Nevertheless, the jury decision in *Gilgunn* suggests some public support for the concept of futility.

How the debate over futility will be resolved is uncertain. Because patient autonomy is so widely accepted in the United States, because national health insurance does not exist there, and because patients and families are suspicious of managed care organizations, it seems unlikely that American physicians will soon be granted a mandate to restrict services on the basis of futility. This is not the case in other countries, however, where resources are limited, national health insurance exists, and physicians implicitly and explicitly are allowed to ration care.⁷¹ Whether physicians will continue to exercise this and other prerogatives if American-style patient autonomy becomes more prevalent in their countries remains to be seen.

JUSTIFICATION FOR ADMINISTERING PALLIATIVE CARE

The U.S. Supreme Court has provided ethical and legal justification for the administration of palliative care at the end of life, in the cases of *Washington v. Glucksberg*⁷² and *Vacco v. Quill*.⁷³ These cases dealt with the constitutionality of laws prohibiting physician-assisted suicide in the states of Washington and New York. In *Glucksberg*, the Court decided that terminally ill patients do not have a liberty interest in committing suicide or in receiving a physician's assistance in committing suicide because of the long tradition of prohibiting suicide in the United States and because of the states' legitimate interest in continuing to make suicide illegal. In *Vacco*, it distinguished between assisted suicide and withholding and withdrawal of life support. "Everyone, regardless of physical condition, is entitled, if competent, to refuse lifesaving medical treatment; no one is permitted to assist a suicide," the Court wrote. "When a patient refuses life-sustaining medical treatment, he dies from an underlying fatal disease or pathology; but if a patient ingests lethal medicine prescribed by a physician, he is killed by that medication."

In *Glucksberg* and *Vacco*, five justices reasoned that Washington and New York could prohibit assisted suicide because these states had no barriers that prevented patients from receiving medications to relieve pain and suffering. However, as Justice Breyer wrote, "Were state laws to prevent the provision of palliative care, including the administration of drugs as needed to avoid pain at the end of life, an action against such law might be called for by the Supreme Court." Through this and other statements, a majority of the justices suggested that being free of pain while dying was a liberty interest protected under the Constitution.⁷⁴

The Supreme Court distinguished assisted suicide from palliative care in *Glucksberg* and *Vacco* by accepting the ethical principle of double effect. Under this rule, acts such as giving sedatives and analgesics that lead to morally good effects, such as the relief of suffering, are permissible even if they produce morally bad effects, such as the hastening of death, provided that only the good effect is intended. The morally bad effect may be foreseen in that physicians are aware of its possibility and even its likelihood, but they may not wish it. The bad effect also may not be a means to the good effect, and the good effect must outweigh the bad one; that is, risking death is reasonable in palliating a terminally ill patient only if there are no less risky ways of relieving suffering.⁷⁵

The Supreme Court's approval of palliative care included sanctioning the practice of *terminal sedation*, in which patients are rendered unconscious while life-sustaining therapies, including nutrition and hydration, are withdrawn. Under *Vacco*, a state may allow terminal sedation if it is "based on informed consent and the double effect. Just as a state may prohibit assisted suicide while permitting patients to refuse unwanted lifesaving treatment, it may permit palliative care related to that refusal, which may have the foreseen but unintended 'double effect' of hastening the patient's death."

Some have argued that the rule of double effect has many shortcomings as an ethical guideline, in particular

because it overlooks the complexity of human intention.^{76,77} Such complexity was demonstrated in a study of the administration of sedatives and analgesics during the withholding and withdrawal of life support in two ICUs.⁷⁸ In this study, physicians indicated that they ordered these agents primarily to decrease pain, anxiety, and dyspnea—but also to hasten death—in 39% of critically ill patients. In another investigation, 16% of a sample of ICU nurses reported that they had engaged in assisted suicide or euthanasia while trying to relieve patient suffering, often without physicians' knowledge.⁷⁹

Just as some physicians and nurses have mixed motives in caring for dying patients, so do some family members want to ease suffering and hasten death simultaneously in their relatives. That such motivation is widespread presumably accounts for the fact that few physicians who are suspected of participating in assisted suicide or euthanasia have been punished through the criminal justice system in the United States.⁸⁰ In general, physicians and other caregivers are unlikely to be prosecuted or even criticized if they act compassionately in administering sedatives and analgesics to treat distressing symptoms in dying patients and do so with informed consent.

In *Glucksberg* and *Vacco*, the Supreme Court did not judge the laws prohibiting physician-assisted suicide in Washington and New York to be unconstitutional. Nevertheless, it also did not prevent other states from permitting physician-assisted suicide if they chose to do so. Physician-assisted suicide was legalized in Oregon in 1997 under that state's Death with Dignity Act. Experience over the subsequent 2 years indicated that few patients requested lethal medications, that physicians granted few requests, and that palliative interventions led some, but not all, patients to change their minds about assisted suicide.⁸¹ By and large, the decision to request and use a prescription for lethal medication stemmed from patients' concern about loss of autonomy or control of bodily functions, not from fear of intractable pain or financial loss.⁸²

Physician-assisted suicide (in which physicians prescribe potentially lethal medications that patients themselves can take) and euthanasia (in which physicians actually administer the medications) are practiced in several European countries.⁸³ Although none of these countries has legalized the practices, physicians in the Netherlands have not been punished for performing them since 1991, when a national study revealed that assisted suicide and euthanasia were being performed.⁸⁴ Instead, Dutch physicians are required to report all cases in which they administered or supplied drugs with the explicit intent of hastening death. Patient requests for assisted suicide or euthanasia rose from 8900 in 1990 to 9700 in 1995 and remained stable at 9700 in 2003 according to one Dutch study.⁸⁵ Assisted suicide was listed as the cause of death on only 0.2% of all death certificates in the Netherlands during the same years. In 1990, 64% of Dutch physicians thought that patients have a right to decide about their own life or death; the percentage of physicians was the same in 1995 but fell to 56% in 2001. These data suggest that, in the Netherlands as in Oregon, the demand for assisted suicide has not increased; in fact, over time, Dutch physicians appear to have grown more reluctant in their attitude toward this practice. How common assisted suicide will become in other European

countries and how their laws will deal with these practices are unclear.

MEDICAL DECISION MAKING AT THE END OF LIFE

TWO MODELS OF THE PHYSICIAN-PATIENT RELATIONSHIP

Medical decisions may be made by physicians, patients, their families, or other surrogates alone or in combination. How decisions are actually made depends in large part on the model of the physician-patient relationship that is used.

Perhaps the oldest model is *paternalistic*; this model has also been called parental or priestly. According to it, physicians act as guardians in defining what their patients' interests are and then serving these interests as they see fit, with little or no input from the patients themselves.⁸⁶ With pediatric patients, the families' input similarly might not be sought or might be disregarded. The paternalistic model overlooks the strong social norm of respect for patient autonomy and the reality that in pluralistic societies it is unlikely that physicians can reliably discern what treatments most advance the interests of their diverse patients. The paternalistic model once dominated medical decision making at the end of life in the United States. In fact, the early cases such as *Bartling*, *Bouvia*, and *Quinlan* were brought because physicians and hospitals were unwilling to let patients or surrogates refuse therapy. It is ironic—and perhaps a cautionary tale about the limits of medical paternalism—that some physicians today demand that patients and families forgo treatment that other physicians once insisted they accept.

In another model, the *deliberative* or shared model, physicians and patients/surrogates collaborate to help patients define their health-related values, discuss treatment options, and together decide which alternative is best. This process is more than the mere passing of information: It is a moral deliberation, based on a mutual understanding of the medical facts and the patient's values.⁸⁷ The shared model of medical decision making is best suited for situations in which physicians, patients, and families have adequate time to deliberate, when reasonable treatment options exist, and when the best course of action may vary according to patients' values and preferences. Evidence from audiorecording ICU family conferences suggests that the process of shared decision making about life support for incapacitated, critically ill patients is often suboptimal.⁸⁸ For example, clinicians frequently failed to explain principles of surrogate decision making, elicit patients' values and preferences, and discuss reasonable treatment options, including a purely palliative approach to care.⁸⁹⁻⁹²

Medical decision making and the attitudes that underlie it vary from country to country. For example, although the shared model is gaining popularity in France, the paternalistic model is still sometimes employed at the end of life in ICUs there. Physicians are granted legal decision-making prerogatives in these ICUs that are not permitted for their American counterparts. Furthermore, French families have had no legal right to make decisions for patients who cannot

make decisions for themselves.⁹³ Variations in attitudes also exist within a given country depending on its ethnic and cultural composition. For example, in one study in the United States, Korean Americans and Mexican Americans were significantly less likely than European Americans and African Americans to believe that a patient should be told the diagnosis of metastatic cancer or that the patient should make the decision about the use of life-sustaining therapy.⁹⁴ In another study, African Americans were more likely than European Americans to want to be kept alive on life support.⁹⁵ Interviews of these African Americans subjects documented a deep distrust of the health care system and a fear that access to health care was based on one's ability to pay.

IMPORTANCE OF PHYSICIAN, PATIENT, AND FAMILY COMMUNICATION

Of course, American families would not need to be so involved in medical decision making in the ICU setting if physicians facilitated such decision making when the patients' diseases were less advanced and they could speak for themselves.⁹⁶ Yet SUPPORT⁹⁷ and other studies have shown that physicians and patients rarely discuss end-of-life issues in advance of the patients' deterioration, even when patients reside in nursing homes. A study of patients with severe COPD enrolled in pulmonary rehabilitation revealed that almost all had health concerns, the most common of which was fear of increasing dyspnea.⁹⁸ Although many of the patients had concerns about being intubated, only a minority had completed an advance directive describing their choices. Furthermore, although the patients generally wanted discussions with their physicians, only 19% had such discussions, only 15% had discussed life support, and only 14% thought that their physicians understood their end-of-life wishes.

Why patients with chronic and terminal diseases do not discuss end-of-life care with their physicians has been the subject of several investigations. In the study of patients with COPD enrolled in pulmonary rehabilitation, those patients who had not had discussions gave the most important reasons as their own procrastination and the fact that their physicians had not brought up the topic.⁹⁸ When these patients participated in an end-of-life educational intervention as part of their rehabilitation, they were more likely to pursue such discussions with their physicians and to complete durable powers of attorney for health care.

In another study of patients with advanced AIDS, structured interviews of the patients and their physicians were used to identify barriers to communication.⁹⁹ Patients who had not had discussions with their physicians about end-of-life care most frequently agreed that, "I don't like talking about getting very sick" and "I would rather concentrate on staying alive than talking about death." Physicians who did not initiate discussions most often agreed that, "There is too little time during our appointments to discuss everything we should" and "I worry that discussing end-of-life with [patient name] will take away his or her hope." Many physicians in this study acknowledged that they felt uncomfortable discussing end-of-life issues, suggesting that their own discomfort was as important as the lack of time for discussions in inhibiting communication.

Limited communication between physicians and patients was also reported in SUPPORT.⁹⁷ Furthermore, SUPPORT revealed that communication was frequently inadequate between physicians and the families of critically ill patients. This finding was corroborated by a study from an ICU in France in which half the families of critically ill patients reported the same inadequacy.¹⁰⁰

A follow-up investigation from that and other ICUs in France indicated that family satisfaction with their relatives' care was due in part to their being of French descent and having a language and cultural values similar to those of the ICU caregivers.¹⁰¹ Family satisfaction also related to information provided by hospital physicians, a patient-to-nurse ratio of 3:1 or less, knowledge of the specific role of each caregiver, help from the family's own physician, sufficient time spent giving information, and an absence of perceived contradictions in information provided by caregivers.

In a study from one U.S. hospital, families were interviewed about their experiences in the ICU and the decision-making process for withholding or withdrawing life support.¹⁰² They reported a high incidence of conflicts, the vast majority of which were between themselves and physicians. The conflicts most often involved problems in communication or perceived unprofessional behavior, such as disregarding the primary caregiver in treatment decisions. These families identified pastoral care and prior discussion of treatment preferences as sources of psychological support. They appreciated lenient visiting hours and the availability of family conference rooms. Most of the families singled out attending physicians as the preferred source of information and reassurance.

IMPROVING COMMUNICATION AND THE QUALITY OF CARE AT THE END OF LIFE

Several strategies have been demonstrated to improve various aspects of decision making and surrogates' psychological outcomes in ICUs. Distribution of a family information leaflet in the ICUs improved family understanding of how the units functioned and increased their satisfaction with the care given therein.¹⁰³ Intensive communication achieved through proactive, frequent family meetings led by attending physicians increased family satisfaction and also decreased ICU length of stay among patients who died.¹⁰⁴ A brief communication intervention in French ICUs for families of patients judged to be certain to die resulted in improved bereavement outcomes.¹⁰⁵

Although the intervention decreased negative bereavement outcomes, it did not contain strategies to improve the quality of decision making. A large, randomized, controlled trial of ethics consultations¹⁰⁶ and two single-center, non-experimental studies of palliative care consultation^{107,108} addressed these issues; these interventions yielded shorter ICU length of stay among nonsurvivors, but there was no assessment of whether the intervention improved the patient-centeredness of end-of-life decisions or improved family outcomes.

UNDERSTANDING WHAT PHYSICIANS, PATIENTS, AND FAMILIES NEED AT THE END OF LIFE

End-of-life care could be optimized if the needs of the parties involved in the dying process were better understood. In this regard, a survey of seriously ill patients, recently bereaved families, physicians, and other caregivers revealed that decisions about treatment preferences, knowing what to expect about one's physical condition, and preparation for death were important to all four groups at the end of life.¹⁰⁹ Other important needs were sharing time with family and friends; being kept clean; being free of pain, anxiety, and dyspnea; and being treated as a "whole person." Patients also rated as important being mentally aware, coming to peace with God, not being a burden to their families, being able to help others, praying, having funeral arrangements planned, and gaining a sense of completion in life (Table 104-2).

The needs of families have also been assessed in several studies using a survey tool called the Critical Care Family Needs Inventory. In an overview of recommendations for end-of-life care in the ICU, the Ethics Committee of the Society of Critical Care Medicine¹¹⁰ combined these studies to determine what these needs are. Overall, family needs include being with the dying patient, being helpful to that patient, being informed of the dying patient's changing condition, understanding what is being done to the patient and why, being assured of the patient's comfort, being comforted, having an opportunity to express emotions, being assured that the family's decisions were right, finding meaning in the patient's death, and having personal needs attended to during the dying process.

Unfortunately, the needs of physicians and others who care for dying patients have not been well addressed.

Nevertheless, at a minimum, all caregivers probably need to feel comfortable during the dying process, to gain experience from it, to feel supported by their colleagues and by their institutions, and to have opportunities for bereavement themselves. Nurses, respiratory therapists, social workers, and clergy who work alongside physicians want to know that the physicians respect them, provide them with adequate information, take their opinions into account, and engage in proper decision-making practices at the end of life.¹¹¹

PROVIDING APPROPRIATE SETTINGS FOR DYING PATIENTS

Under the deliberative model of the physician-patient relationship, physicians are obligated to help patients understand their conditions, explore their therapeutic options, and decide what is best for them. Essential to this relationship is preparing patients for death when appropriate. Such preparation should include consideration of whether the patients' interests are best served by hospital and ICU admission when death is imminent, assuming that impending death can be identified. Many patients, especially those with COPD and other chronic diseases that allow time for advance planning as death approaches, decide to die in a hospice or at home if given the opportunity.

Terminal patients may choose a trial of attempted restorative treatment in the hospital or undergo it because their wishes are not known. If the trial fails, such patients should be allowed to die in an environment that is comfortable for them and their families. A private room with enough space to accommodate visitors might be such an environment. Visiting hours should be relaxed, if necessary, to allow families and friends to spend as much time as they wish with dying patients. Some hospitals have separate palliative care units for this purpose. Others offer palliative care teams or services that consult throughout the hospital.^{112,113}

Table 104-2 Factors Important to Patients and Family at End-of-Life

PHYSICAL NEEDS

Maintaining hygiene
Release from breathing difficulties
Remaining conscious and clearheaded to the end
Physical independence to the end

EMOTIONAL NEEDS

Regular update on medical condition
Opportunity to discuss fears and anxieties
Telling the absolute truth to patients
Involving patients in care policy and decisions

SPIRITUAL NEEDS

Being at one with God
Praying
Conversation with cleric about meaning of death

SOCIAL NEEDS

Capacity to help others

EMOTIONAL AND SPIRITUAL SUPPORT

Reviews of end-of-life care in and outside the ICU have emphasized the importance of providing emotional and spiritual support to dying patients and their families.¹¹⁴ Physicians contribute to this support, of course, and their regular communications and presence at the bedside are greatly appreciated. Nurses, social workers, clergy, and other members of the health care team deliver most of the support, however. Occasionally, patients or their families request that friends, caregivers, and religious persons from outside a particular institution provide consultations or participate in bedside rituals or observances. These should be allowed, if not encouraged, unless they interfere with patient care.

End-of-life care may extend after death in that physicians, nurses, and others who have helped the patients' families when the patients were alive have much to offer them thereafter. Advising on the disposition of bodies, reporting the

Adapted from Natan MB, Garfinkel D, Shachar I: End-of-life needs as perceived by terminally ill older adult patients, family and staff. *Eur J Oncol Nurs* 14:299–303, 2010.

results of autopsy studies, coordinating burials and funeral services, and attending funerals are among the professional responsibilities of caregivers that are greatly appreciated by families. These responsibilities can be assumed by independent bereavement follow-up services, which have been described at one hospital.¹¹⁵ Alternatively, caregivers who have established personal relationships with families in the ICU and other settings may maintain them after the patients' death.

Physicians, nurses, and other caregivers have their own emotional and spiritual needs, of course, and caring for dying patients and their families exacts an appreciable toll on them. Because of this, caregivers themselves should have opportunities to grieve. Conferences scheduled after patients die provide both an opportunity for bereavement and a mechanism for evaluating the processes of withholding and withdrawal of life support and of administering palliative care to them. Such evaluation may lead to improvements in these processes for future patients.

SYMPTOM MANAGEMENT

WHY SYMPTOMS MAY BE POORLY MANAGED

Management of pain and other symptoms is a traditional role and responsibility of the medical profession. Nevertheless, patients too frequently die with pain and other distressing symptoms. Nearly 50% of SUPPORT patients or their surrogates interviewed after study enrollment reported that the patients experienced pain during hospitalization.¹¹⁶ Nearly 15% reported extremely or moderately severe pain at least half the time, and many of those patients with pain were dissatisfied with its control. Uncontrolled pain was most common among patients with more dependence on others in activities of daily living and who had more comorbid conditions, more anxiety, more depression, and a poorer quality of life.¹¹⁶

The poor management of pain and other symptoms in some patients is probably due in large part to the strong emphasis placed on the diagnosis and treatment of diseases rather than on the relief of symptoms. Palliative care reverses this emphasis and, when properly applied, should help increase patient comfort at the end of life. Nevertheless, the transition from restorative to palliative care is far from seamless for many patients. In this regard, it is difficult for patients and their families to know when to stop requesting treatment, just as it is for physicians and other caregivers to stop recommending life-sustaining therapies.

Pain and other symptoms may also be poorly managed because they are subjective experiences that are not easily assessed by objective methods. Pain and sedation scales have been developed to quantify the levels of pain and anxiety among patients who can communicate. Nevertheless, some patients cannot adequately communicate these sensations, either because they cannot find the words or because they are intubated and sedated. To detect pain in these patients, physicians and other caregivers must attend to patient grimacing and other admittedly nonspecific manifestations of pain, including tachycardia and hypertension. Although bispectral analysis of the electroencephalogram has been used to assess the level of sedation in ICU patients,

the correlation of this technique with sedation scales and, most important, with the subjective experiences of patients is unclear.¹¹⁷

Another reason that symptoms are poorly managed at the end of life is that patients differ in their desire for symptom relief. Some patients value symptom relief highly and would prefer to be rendered unconscious rather than to experience pain, anxiety, or dyspnea, especially at the end of life. Others, however, would be willing to tolerate these symptoms or have them mitigated only slightly in order to stay awake. Dying patients may find it difficult to titrate sedatives and analgesics to their desired level of consciousness, although they should be encouraged to do so. Physicians and caregivers may find it even more difficult to achieve the ideal level of sedation and analgesia for patients who cannot communicate or administer drugs to themselves.

Finally, symptoms may be inadequately managed because physicians and other caregivers feel uncomfortable about giving high doses of sedatives, analgesics, and other mood-altering agents. In some instances, this discomfort stems from a reluctance to cause drug addiction in dying patients, a concern irrelevant to the patients' condition. Other discomfort results from awareness that the agents may hasten death by depressing not only consciousness but also respiratory and cardiovascular function. That the U.S. Supreme Court has justified the administration of sedatives and analgesics under the principle of the double effect should help put caregivers at ease. Although one third of physicians in one study who ordered these agents to dying adult patients did so in part to hasten death,⁷⁸ virtually all the physicians in a comparable study¹¹⁸ conducted in a pediatric ICU viewed hastening death only as an "acceptable, unintended side effect."

MANAGEMENT OF PAIN

Indirect approaches to pain control include nonpharmacologic means. For example, placing patients in a quiet environment where friends and family can visit may diminish the sense of pain, as may the proper treatment of anxiety and depression. Although respiratory depression due to drugs or underlying disease is usually undesirable in patients with COPD, the encephalopathy that results from the hypercapnia and hypoxia may be tolerated, if not favored, in terminal patients because it attenuates pain. Similarly, patients who forgo nutrition and hydration at the end of life may develop a euphoria that has been attributed to the release of endogenous opioids or the analgesic effects of ketosis.

Direct approaches to pain control generally center on the use of opioids, most commonly morphine. In addition to causing analgesia, morphine induces some degree of sedation, respiratory depression, constipation, urinary retention, nausea, and euphoria. It also produces vasodilation, which may cause hypotension, in part through the release of histamine. Fentanyl, a synthetic opioid that is approximately 100 times more potent than morphine, does not release histamine and, therefore, causes less hypotension. Hydromorphone, a semisynthetic morphine derivative, is more sedating than morphine and produces little euphoria.¹¹⁹

Morphine, fentanyl, and hydromorphone can be administered orally, subcutaneously, rectally, or intravenously. Opioids are usually given by the intravenous route to ICU patients, including those who are dying. These agents may be administered to inpatients and outpatients alike through the technique of patient-controlled analgesia. Long-acting oral preparations of morphine and hydromorphone are available for outpatients. Fentanyl can be administered orally in the form of a lollipop. It can also be given by the transcutaneous route, which makes this agent particularly suitable for patients who have difficulty with oral medications.

Opioids ideally should be administered in anticipation of pain and not afterwards. The optimal doses of these drugs given for pain relief are unknown and certainly vary among patients. Nevertheless, opioids generally should be started in relatively low doses if respiratory depression and other side effects are to be avoided and titrated upward until their analgesic effect is realized. In reports of critically ill patients undergoing the withholding and withdrawal of life support in both adult and pediatric ICUs, opioids were used in doses sufficient to achieve pain relief that caregivers considered adequate.⁷⁸ In dying patients, the use of opioids should not be limited by some arbitrary amount but by the balance between analgesia and any undesirable side effects.

MANAGEMENT OF ANXIETY

As in the case of pain, anxiety and its physical manifestation agitation can be managed nonpharmacologically. If drugs are required, benzodiazepines and propofol are preferred. Benzodiazepines cause anterograde amnesia in addition to anxiolysis, and they exert a synergistic sedating effect with opioids. Benzodiazepines also cause hypotension and cardiac depression, especially when administered quickly and in high doses. Lorazepam, an intermediate-acting agent, can be given by the oral, intramuscular, or intravenous route; when given intravenously, it can be done so by bolus or by constant infusion. Midazolam, which is short-acting, is usually administered intravenously by constant infusion, although boluses may be required when therapy is initiated.¹²⁰

Propofol is an intravenous general anesthetic agent with sedating, amnestic, and anxiolytic properties when administered in subanesthetic doses. In such doses, propofol is similar to midazolam in that it is usually given by constant infusion after bolus injection. The drugs are also comparable in the sedation they produce, although propofol has a greater propensity to cause hypotension.¹²⁰ Neither propofol nor midazolam is appropriate for the management of anxiety in outpatients and, in hospitals, their continuous use may be restricted to the ICU.

MANAGEMENT OF DELIRIUM

Delirium may be confused with anxiety because it can also cause agitation. The confusion is clinically important both because the conditions are treated pharmacologically with different drugs and because the drugs used to treat anxiety can exacerbate delirium.¹¹³ Delirious patients should be helped to obtain regular sleep, should be oriented regularly

to their environment, and should avoid benzodiazepines, which cloud consciousness. Haloperidol, a butyrophenone neuroleptic agent, is widely used to treat delirium in critically ill patients. It may be given orally, rectally, intramuscularly, or intravenously. Haloperidol may cause QT prolongation on the electrocardiogram and should be used cautiously with other agents that have a similar effect. Haloperidol can also cause rigidity, restlessness, and other dyskinesias.

MANAGEMENT OF DYSPNEA

Especially in the early stages of disease, dyspnea should be understood and managed according to its underlying pathophysiology^{121,122} (see Chapter 29). For example, patients with moderate to severe COPD may benefit from oral bronchodilators that decrease airflow resistance, inhaled corticosteroids that decrease airway inflammation, and lung volume reduction surgery that decreases hyperinflation. These patients may also become less dyspneic through exercise training and the emotional support available through pulmonary rehabilitation programs.¹²³ At the same time, patients with lung cancer may feel less breathless after drainage of malignant pleural effusions or placement of stents to overcome airway obstruction.

In patients with far advanced lung disease, attention to pathophysiologic mechanisms is less important, and treatment is more palliative than restorative. Bronchodilators may not reduce breathlessness in such patients, corticosteroids may cause more unwanted side effects than symptom relief, and lung reduction surgery may prove fatal. Patients with COPD who are dying, at home or in hospice, do not benefit from exercise training and may be too breathless to attend pulmonary rehabilitation programs; these patients should be encouraged to use wheelchairs and to rest. In most terminal cancer patients, malignant effusions and airway obstruction should not be diagnosed or treated.¹²¹

Patients with chronic respiratory failure of whatever cause should receive supplemental oxygen, which has been shown both to increase survival and to decrease breathlessness.¹²⁴ In the United States, Medicare reimbursement for long-term oxygen therapy is based on physiologic criteria (e.g., arterial $PO_2 < 55$ mm Hg while breathing room air), not symptomatology. Despite this fact, many patients use oxygen primarily to relieve dyspnea, and hospice patients do not have to meet physiologic criteria to receive reimbursement. Supplemental oxygen is usually started in low doses (e.g., 1 to 3 L/min) and titrated to effect. The results of titration are difficult to predict inasmuch as neither the flow rate nor the route of administration of oxygen determines its impact on breathlessness.¹²⁰ Furthermore, air may relieve dyspnea as well as oxygen does in patients with advanced malignancy.¹²⁵ In addition, breathless patients are frequently relieved by exposure to fresh air in the outdoors or during automobile rides with the windows down. Those who are bedridden may benefit from using fans to blow air over their faces.¹²¹

Opioids such as oral morphine have been demonstrated to increase exercise tolerance acutely and to alleviate dyspnea in occasional patients with COPD.¹²⁶ Nevertheless, the long-term administration of sustained-release

morphine has not been shown to be superior to placebo in reducing breathlessness in such patients, most of whom reported nausea, constipation, and other adverse effects.¹²⁷ Although many patients become tolerant to these adverse effects over time, opioids probably should be used only on a trial or as-needed basis for patients with recalcitrant dyspnea who do not respond to oxygen or air. However, because their analgesic properties are undisputed, these agents may be particularly useful in patients who have pain in addition to breathlessness, such as those with lung cancer.¹²¹ Although the use of morphine and other opioids to relieve dyspnea in patients with ARDS and other causes of acute respiratory failure is widespread and seems reasonable, this practice is not supported by research studies.

Benzodiazepines such as alprazolam have been shown to reduce dyspnea in some patients with COPD.¹²⁸ Yet these agents may also cause drowsiness, uncoordination, and dysphoria, and they should probably be used only in outpatients whose dyspnea is not relieved by oxygen and opioids.¹²¹ As is true of opioids, benzodiazepines and propofol are commonly used to reduce dyspnea, in addition to anxiety, among patients with acute respiratory failure, particularly those receiving mechanical ventilation. Again, this practice appears reasonable, especially if the patients are not experiencing unwanted side effects. Nevertheless, the benefits of treating dyspnea with sedatives in ICU patients have not been demonstrated scientifically.

MANAGEMENT OF NAUSEA AND VOMITING

Nausea and vomiting may result from systemic illnesses such as diabetes, renal failure, hypercalcemia, adrenal insufficiency, and viral infections. These symptoms may also be caused by central nervous system disorders, including cerebral metastases and other conditions that increase intracranial pressure; primary gastrointestinal diseases such as gastric outlet obstruction; and a variety of drugs, including theophylline, phenytoin, opioids, antibiotics, and chemotherapeutic agents. Nausea and vomiting may remit with treatment of the disorder or with discontinuation of the drugs that cause them. Because eating can increase nausea, patients may benefit by being placed on a nothing-by-mouth status or undergoing gastric decompression. Clear liquid diets may be administered to patients as tolerated. Supplemental oxygen has been shown to reduce the incidence of postoperative nausea and vomiting.¹²⁹

Patients with nausea and vomiting who do not respond to more conservative measures may be candidates for prophylactic or therapeutic antiemetic therapy, which can be given orally, intramuscularly, intravenously, or in suppository form. Among the older antiemetics are dexamethasone and other corticosteroids; butyrophenones such as haloperidol and droperidol; chlorpromazine, promethazine, prochlorperazine, and other phenothiazines; and muscarinic receptor antagonists such as scopolamine, which is particularly helpful in patients with vestibular symptoms. Of these agents, dexamethasone, droperidol, and promethazine are the most widely used.

Newer antiemetics include the serotonin receptor antagonists ondansetron, dolastron, granisetron, and tropisetron. These drugs have been tested primarily in the postoperative period and among patients who have received

chemotherapy or radiation therapy. Because of their expense, they probably should be used only after other agents are found to be unsuccessful in preventing or relieving symptoms.¹³⁰ Cannabinoids, administered either orally or through smoking the *Cannabis sativa* (marijuana) plant, are as effective as older antiemetic agents such as chlorpromazine, prochlorperazine, and metoclopramide in reducing nausea and vomiting caused by chemotherapy. Nevertheless, although some patients welcome the sedation and euphoria they experience with cannabinoids, others complain of dizziness and dysphoria.¹³¹

MANAGEMENT OF HUNGER AND THIRST

People eat food and drink fluids to relieve hunger and thirst and to sustain metabolic processes. Food and fluids are administered to hospitalized patients under the assumption that they are staples of life and components of routine medical and nursing care. Under this assumption, some have argued that a patient's refusal of nutrition and hydration is tantamount to suicide and that food and fluids should be administered to all patients other than those who reject them because of intolerable pain and suffering in the last moments of life.¹³² Others have noted that voluntary forgoing of nutrition and hydration by terminal patients represents only a refusal of unwanted treatment that is ethically and legally justified.¹³³ Still others have argued that force-feeding violates patient autonomy and that voluntary "terminal dehydration" on the part of patients offers substantial advantages over physician-assisted suicide with respect to self-determination, access, and professional integrity.¹³⁴

Of course, patients may desire food and fluids until they die; alternatively, they may choose not to eat or drink. In fact, one study has documented that, in Oregon, where physician-assisted suicide is allowed, many hospice patients forgo eating and drinking, perhaps as an alternative to assisted suicide.¹³⁵ As was the case in this study, another investigation conducted in a comfort care unit demonstrated that most cancer patients either never experienced hunger and thirst or did so only initially during their terminal illnesses.¹³⁶ In the few patients who were symptomatic, hunger, thirst, and dry mouth usually could be alleviated with small amounts of food and fluids or by the application of ice chips or lubrication to the lips. Similar measures can be used in other settings, including the ICU.

WITHHOLDING AND WITHDRAWAL OF LIFE-SUSTAINING THERAPY

WHAT THERAPIES ARE WITHHELD AND WITHDRAWN

Life-sustaining therapies are withheld and withdrawn in many settings. Nevertheless, most of the studies of this process have been conducted in ICUs. These studies, from pediatric and adult ICUs around the world, reveal that, although any and all interventions may be withheld or withdrawn, variation exists in the type, number, and

sequence of interventions forgone.^{21,22,137} In one investigation in an adult ICU in the United States, an average of five separate interventions were forgone per patient.¹³⁸ CPR, intubation and mechanical ventilation, and dialysis generally were the first interventions withheld; thereafter, vasopressors, transfusions, intravenous fluids, parenteral nutrition, antibiotics, and tube feedings were either withheld or withdrawn. Decisions regarding withholding therapy were reached sooner than decisions about withdrawing therapy. Whereas a decision not to intubate a patient was made early for patients not already on ventilators, once patients were on ventilators, decisions to withdraw ventilatory support were generally made late, after several other interventions were first forgone.

Another study in which physicians were surveyed about the withdrawal process indicated distinct preferences about the form of support withdrawn.¹³⁹ From most likely to least likely, the order was blood products, dialysis, vasopressors, parenteral nutrition, antibiotics, mechanical ventilation, tube feedings, and intravenous fluids. Four biases in decision making were also identified. Physicians preferred to withdraw (1) therapies supporting organs that failed for natural, rather than iatrogenic, reasons; (2) therapies that were instituted only recently; (3) therapies resulting in an immediate, rather than a delayed, death; and (4) therapies resulting in a delayed death only when faced with diagnostic uncertainty.

WITHHOLDING AND WITHDRAWAL OF INTUBATION AND MECHANICAL VENTILATION

Intubation and mechanical ventilation are often used in patients with acute, chronic, or acute-on-chronic respiratory failure and are among the therapies most commonly withheld or withdrawn. As noted earlier, some patients with advanced COPD and other causes of chronic respiratory failure have concerns about intubation and mechanical ventilation and decide against these therapies in advance of decompensation. Nevertheless, other patients with chronic respiratory failure request intubation and mechanical ventilation or are intubated and ventilated—either in the field, in the emergency department, or in the ICU—without having decided on their wishes or having communicated them. Similarly, patients with acute respiratory failure often end up on ventilators because their conditions are assumed to be reversible. When they and their counterparts with chronic respiratory failure do not improve, intubation and mechanical ventilation may be withdrawn. One study revealed that the strongest determinants of withdrawal of mechanical ventilation in critically ill patients were the physicians' perception that the patients preferred not to use life support, the physicians' prediction of a low likelihood of survival in the ICU and a high likelihood of poor cognitive function, and the use of inotropes or vasopressors.¹⁴⁰

How intubation and mechanical ventilation are withdrawn varies among institutions. One approach is rapid extubation: the patient is given analgesics and sedatives, and both the endotracheal (or tracheotomy) tube and the ventilator are removed. Patients are then given either supplemental oxygen or, more commonly, room air to breathe. Rapid extubation is direct and, in the pediatric setting, it

offers the potential advantage of allowing parents to hold their infants without being encumbered by the ventilator or its tubing. A potential disadvantage is that patients may appear distressed due to upper airway obstruction after the tube is removed.

A second process, called *terminal weaning*, involves decreasing the inspired oxygen fraction, the ventilator rate, the level of positive end-expiratory pressure, or some combination of these variables before the ventilator is removed. Patients are given drugs during this process, and they most often die before extubation. First described in 1983, this technique was developed in order to avoid abruptly discontinuing treatment in such a way that "might be interpreted with intent to kill" and might make patients and their families uncomfortable.¹⁴¹ The first part of this rationale is not relevant today because the differences between terminal weaning and euthanasia have been delineated by the U.S. Supreme Court. Nevertheless, terminal weaning still may cause less discomfort than rapid extubation by avoiding upper airway obstruction.

The relative advantages and disadvantages of rapid extubation and terminal weaning have been debated. They have not been compared scientifically, although one study of what was called "rapid terminal weaning" demonstrated that patients could be kept comfortable during the procedure with relatively low doses of opioids and benzodiazepines.¹⁴² A survey of critical care physicians indicated that 15% of respondents almost never withdrew intubation and mechanical ventilation from dying patients.¹⁴³ Of physicians who did, 13% preferred rapid extubation, 33% preferred terminal weaning, and the remainder used both methods. Reasons for preferring rapid extubation included the directness of the action, family perceptions, and patient comfort. Reasons for preferring terminal weaning included patient comfort, family perceptions, and the belief that terminal weaning was less abrupt.

When intubation and mechanical ventilation are withdrawn, most patients with respiratory failure die of their underlying diseases. Nevertheless, some survive, and their survival should not be prevented by drugs that hasten death. At the same time, even patients who are too sick to survive should not receive drugs that interfere with observing tachypnea and other signs that may signal the need for symptom relief. For these reasons, although sedatives and analgesics may be given to relieve suffering, neuromuscular blocking agents should not be introduced to patients while intubation and mechanical ventilation are withdrawn. Furthermore, if the patients are already receiving them, a common situation with infants, these agents should be continued only if two requirements are met. First, death is expected to be both rapid and certain after removal of the endotracheal tube, the ventilator, or both. Second, the burdens to patients and families of waiting for neuromuscular blockade to diminish to a reversible level exceed the benefits of allowing better assessment of the patients' comfort and possible interaction with their families.

ACKNOWLEDGMENTS

Key Points

- End-of-life care is a combination of palliative treatment and withholding and withdrawal of life-sustaining therapy provided to patients who are terminally ill, including those with acute, chronic, and acute-on-chronic respiratory failure.
- End-of-life care is justified by the ethical principles of beneficence, nonmaleficence, autonomy, and justice and by the legal right of informed patients to consent to or refuse any or all therapy, including that which sustains life.
- The legal right of consent or refusal may be exercised by patients themselves or by their family members and legally appointed surrogates through substituted-judgment and best-interests standards.
- End-of-life care is enhanced by a shared model of medical decision making and by intensive communication among patients, family members, and caregivers. Such care should attend to the needs of patients, families, and caregivers alike.
- When patients or their surrogates request treatments that clinicians believe are potentially inappropriate or futile, clinicians should generally pursue a stepwise approach to dispute resolution rather than unilateral action, including intensive communication with the patient/surrogate, involvement of expert consultants (e.g., ethics consultants), review by a hospital committee, and offering the opportunity to seek transfer to another facility.
- The components of end-of-life care include providing appropriate settings for dying patients; supplying emotional and spiritual support; managing such symptoms as pain, anxiety, delirium, dyspnea, nausea and vomiting, and hunger and thirst; and removing unwanted therapies.

INTRODUCTION

Patients with advanced chronic respiratory disease frequently have distressing symptoms, limitations in exercise ability, and reductions in health and functional status that persist despite optimal pharmacologic management. Pulmonary rehabilitation complements standard medical therapy and can lead to improved exercise and functional capacity, decreased dyspnea, improved health status, and (perhaps) reduced risk of premature morbidity and mortality. Pulmonary rehabilitation is now accepted as the standard of care for patients with *chronic obstructive pulmonary disease* (COPD), and it has been incorporated into international guidelines for this disease.^{1,2} Although pulmonary rehabilitation was designed and is applied primarily to symptomatic patients who are limited due to the burden of COPD, the same fundamental principles appear applicable to other chronic respiratory disease states.

DEFINITION AND GOALS

The American Thoracic Society and European Respiratory Society define pulmonary rehabilitation as “a comprehensive intervention based on a thorough patient assessment followed by patient-tailored therapies that include, but are not limited to, exercise training, education, and behavior change, designed to improve the physical and psychological condition of people with chronic respiratory disease and to promote the long-term adherence to health-enhancing behaviors.”³ As this definition indicates, there is now a strong evidence base demonstrating the effectiveness of pulmonary rehabilitation, and it should be considered in the general care of patients with chronic respiratory disease.

Pulmonary rehabilitation and exercise training have been erroneously considered to be equivalent. Although exercise training is a necessary component of pulmonary rehabilitation, other interventions are integral to a rehabilitation program. These include patient assessment, education (especially involving collaborative self-management

strategies), nutritional intervention, psychosocial support, and a discussion of advance directives. Promotion of activity in the home and community settings is becoming recognized as an essential component in pulmonary rehabilitation. Smoking cessation, breathing retraining, chest physical therapy, oxygen therapy, and adjunctive therapies are also provided for selected individuals.

It may appear paradoxical that pulmonary rehabilitation does not have a significant, direct effect on pulmonary function, yet it provides the greatest improvements in dyspnea, exercise tolerance, and health status of any therapy for COPD. Emerging data suggest that it may also be beneficial for other chronic respiratory diseases. This apparent paradox is explained by the fact that COPD can be considered to be a systemic disease,^{4,5} and comorbidity (such as decreased oxidative capacity of the muscles of ambulation, physical deconditioning, fear of dyspnea-producing activities, improper pacing) contributes to patients' symptoms and disability. The 6-minute walk distance, which reflects the systemic nature of the disease, is therefore a stronger predictor of survival in COPD patients than measurements of airflow limitation such as the *forced expiratory volume in 1 second* (FEV₁).^{6,7} Similarly, the mid thigh cross-sectional⁸ and mid arm cross-sectional areas,⁹ measures of muscle mass, are better predictors of survival than lung function.

Pulmonary rehabilitation is effective in reducing the negative impact of comorbidities. For example, exercise tolerance in COPD is limited by multiple factors, including increased resistive work of breathing (due to breathing through narrowed airways), increased elastic work of breathing (due to static and dynamic hyperinflation), and abnormalities in the muscles of ambulation (leading to lactate production and fatigue at low exercise intensities). Exercise training leads to a decreased ventilatory requirement at a given level of exercise due in part to physiologic changes in the leg muscles. This decrease in ventilatory requirement allows the patient to breathe at a lower respiratory rate during exercise, thereby reducing the effects of dynamic hyperinflation. Thus, pulmonary rehabilitation exercise training leads to increased exercise capacity by its

direct effects on the leg muscles that reduce the ventilatory requirement and its direct effects on dynamic hyperinflation¹⁰ and cardiac output¹¹—despite the fact there is no measurable change in FEV₁.

Comprehensive pulmonary rehabilitation requires contributions from different health care professionals. Physicians, nurses, nurse practitioners, physical therapists, respiratory therapists, nutritionists, and occupational therapists may be involved in a particular program, depending on availability and resources. A physician medical director and a professional pulmonary rehabilitation coordinator are necessary for program certification in the United States. The goals of pulmonary rehabilitation are to reduce symptoms, improve functional status, and reduce health care costs.¹

HISTORY

Pulmonary rehabilitation and its components have been recognized by clinicians as an effective intervention since at least the middle of the 20th century.^{12,13} Since the mid-1990s, it has risen to prominence as a state-of-the-art, scientifically proven intervention for individuals with chronic lung disease. Its current importance as a therapeutic option is underscored by four events:

- Its incorporation as the “best therapy” to which lung volume reduction surgery was compared in the *National Emphysema Treatment Trial* (NETT).¹⁴
- A Cochrane report demonstrating the effectiveness of pulmonary rehabilitation in meta-analyses.¹⁵
- Its endorsement by the *Global Initiative for Obstructive Lung Disease* (GOLD) and its prominent position in the current treatment algorithm for COPD.¹⁶
- Its acceptance as an approved medical benefit in the United States under the *Centers for Medicare and Medicaid Services* (CMS) beginning in January 2010.¹⁷

Over time, what was considered a form of therapy reserved only for patients with the most severe impairment is now recommended for all patients with symptoms that limit their performance and a moderate severity of disease. Before 1991, much of the literature supporting pulmonary rehabilitation consisted of descriptions of comprehensive pulmonary rehabilitation and presentations of uncontrolled, pre-intervention/post-intervention studies showing its effectiveness primarily in reducing hospital utilization.^{18,19} However, in 1991 Casaburi and colleagues²⁰ reported on a study of 19 COPD patients who were randomized to either higher or lower levels of exercise training on a cycle ergometer. Training was 5 days per week for a total of 8 weeks. The patients who trained at lower levels exercised longer, so the total amount of work was roughly equivalent in the two groups. Both levels of training led to significant physiologic benefits manifested by reduced lactic acidosis and ventilatory requirement at the same work rate. However, those who trained at higher intensity had more physiologic benefit than those who trained at lower intensity. Before this study, many believed that patients with advanced COPD, often being ventilatory limited during exercise, could not derive true physiologic benefit from this type of intervention. This was the first randomized, con-

trolled trial to demonstrate that a training effect could result from exercise training, the cornerstone of pulmonary rehabilitation.

In 1994, Goldstein and associates²¹ reported a prospective, randomized, controlled trial of pulmonary rehabilitation. Eighty-nine patients with COPD were randomized to either pulmonary rehabilitation, initially given in an inpatient setting, or conventional medical care. The group that participated in pulmonary rehabilitation had significantly greater increases in the 6-minute walk distance, submaximal cycle endurance time, and health status compared with the group given standard medical care. This was the first of several randomized, controlled trials of pulmonary rehabilitation that established the effectiveness of pulmonary rehabilitation as a treatment option for chronic lung disease.

That same year, Reardon and coworkers²² reported on 20 COPD patients who were randomized either to comprehensive outpatient pulmonary rehabilitation or to a waiting period during which they were given conventional medical care. Rehabilitation led to significant improvements in exertional dyspnea, measured by incremental treadmill exercise testing and by questionnaire-rated dyspnea with daily activities. Exertional dyspnea was reduced at levels of exercise common to activities of daily living, underscoring its clinical meaningfulness. This was the first study to demonstrate the effectiveness of pulmonary rehabilitation on dyspnea, the most important symptom in advanced lung disease. Subsequent studies by O'Donnell and colleagues^{23,24} showed that the reduction in postexercise training dyspnea was associated with decreased ventilatory demand, probably due to physiologic changes in the leg muscles.

In 1995, Ries and associates²⁵ reported on 119 patients with COPD who were randomized either to comprehensive outpatient pulmonary rehabilitation with exercise training or to education alone. Compared with education alone, rehabilitation led to significant relief of dyspnea, maximal exercise capacity, exercise endurance, and self-efficacy for walking. “Self-efficacy” refers to the patient's confidence in successfully managing respiratory symptoms associated with an activity. Positive results declined over time, approaching those of the control group by 18 to 24 months. This was the first large randomized, controlled study showing the effectiveness of outpatient pulmonary rehabilitation on multiple outcomes. The decline in gains made over time underscored the importance of strategies to improve long-term adherence with rehabilitation.

In 1996, Maltais and coworkers²⁶ reported on 11 patients with COPD who were evaluated before and after 36 sessions of high-intensity endurance training. In addition to the expected physiologic training effect including reduced exercise-induced lactic acidosis, exercise training led to increased levels of oxidative enzymes in muscle biopsy specimens. Of additional importance, the improvement in biochemical markers correlated with reduced lactic acid production during exercise. Along with other work, this study showed that exercise training improves skeletal muscle oxidative capacity in COPD patients and that this improvement has clinical value.

In 2000, Griffiths and colleagues²⁷ presented data on 200 patients with chronic lung disease who were randomized to either 6 weeks of multidisciplinary pulmonary rehabilitation

or standard medical management. In addition to showing substantial improvements in exercise performance and health-related quality of life, the pulmonary rehabilitation intervention led to fewer days in the hospital and fewer primary care home visits in the 1-year follow-up period. Thus, this large randomized trial demonstrated that pulmonary rehabilitation led to a substantial reduction in health care utilization, confirming conclusions from earlier uncontrolled studies. A subsequent study from this group²⁸ provided evidence supporting the cost-effectiveness of pulmonary rehabilitation.

A study by Bourbeau and associates²⁹ suggested that a self-management program in the home led to fewer hospital admissions and other health utilization variables and improvement in health status. Subsequent trials have been less consistent, but a recent meta-analysis of 17 studies supports benefits in quality of life, fewer hospital admissions, but no differences in visits to the emergency department or survival.³⁰

In 2005, Casaburi and coworkers³¹ showed that increasing bronchodilation in patients with COPD led to enhanced outcomes from pulmonary rehabilitation. Patients with optimized lung function could exercise at higher intensities and achieve greater increases in exercise capacity. Thus, not only does pulmonary rehabilitation add to the positive outcomes from pharmacologic therapy, pharmacologic therapy also adds to the benefits from pulmonary rehabilitation.

In 2007, joint guidelines from the *American College of Chest Physicians (ACCP)* and the *American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR)*³² summarized the evidence base underlying pulmonary rehabilitation. The document cited strong evidence supporting the effectiveness of pulmonary rehabilitation on improvements in dyspnea and quality of life. There was also substantial evidence supporting its effectiveness in reducing health care utilization and improving psychological outcomes.

Pulmonary rehabilitation is the most effective therapy available for increasing the exercise capacity of patients with chronic respiratory disease. However, its effectiveness in promoting increased activity in the home and community setting was not proved until fairly recently. Increased physical activity is an important outcome because patients with COPD are often sedentary,³³ and lower levels of physical activity are associated with poorer long-term outcomes.³⁴ In 2008, Walker and colleagues³⁵ demonstrated that directly measured activity (from activity monitors) was increased following 8 weeks of pulmonary rehabilitation. This study corroborated results from two other studies that also demonstrated similar positive effects.^{36,37} These studies, therefore, provide strong support for the idea that the increased exercise capacity attained in the pulmonary rehabilitation center translates into increased activity in other settings.

RATIONALE

Pulmonary rehabilitation has a minimal, if any, effect on the abnormal lung function or respiratory physiology of individuals with chronic lung disease. The apparent paradox

is explained by the fact that a considerable portion of the dyspnea and the health status limitations from chronic lung disease results from extrapulmonary effects of the disease, which can respond to treatment. Some of the associated systemic manifestations of chronic lung disease include nutritional depletion,^{38,39} a decrease in lower extremity muscle mass and peripheral muscle weakness and fatigability,^{40,41} alterations in peripheral muscle fiber type,⁴² and a reduction in peripheral muscle oxidative enzymes.⁴³ In addition, poor pacing techniques, maladaptive coping skills, and fear of dyspnea-producing activities result in a vicious circle of further deconditioning and debilitation. Pulmonary rehabilitation is effective in interrupting this cycle, usually resulting in clinically meaningful improvement in multiple areas of importance to the patient, including a reduction in exertional dyspnea and the dyspnea associated with daily activities, improvement in exercise performance and in health status, and reduction in health care utilization.

INDICATIONS

Pulmonary rehabilitation is indicated for individuals with chronic respiratory disease who have persistent symptoms or disability despite standard medical therapy. [Figure 105-1](#) represents the course of patients with lung function limitation over time and the role of pulmonary rehabilitation. Patients are usually referred for one or more of the following symptoms or conditions⁴⁴:

1. Severe dyspnea and/or fatigue
2. Decreased exercise ability
3. Interference with performing activities of daily living
4. Impaired health status
5. Decreased occupational performance
6. Nutritional depletion
7. Increased medical resource utilization

It should be noted that persistent symptoms and/or limitation in these clinical areas—not just the specific physiologic impairment of the lungs (such as a low

Figure 105-1 Change in forced expiratory volume in 1 second (FEV₁) over time in persons susceptible to the effect of cigarette smoking and who develop COPD. The progressive decline results in functional limitation, poor health status, and eventual death. Pulmonary rehabilitation has a role once persistent symptoms or disabilities develop and for as long as patients benefit.

FEV₁ or hypoxemia)—dictate the need for intervention. Furthermore, symptoms, exercise performance, functional status, and health status correlate relatively poorly with pulmonary function abnormalities. Because of this, there are no specific threshold pulmonary function inclusion criteria for pulmonary rehabilitation.

Often the referral to pulmonary rehabilitation has been reserved for advanced lung disease. Although patients in this category can still benefit from the intervention,⁴⁵ referral at an earlier stage would allow more emphasis on preventive strategies such as smoking cessation and would permit exercise training at higher levels of intensity.

Traditionally, pulmonary rehabilitation has dealt primarily with COPD, whereas its effectiveness for other pulmonary conditions has received less attention.⁴⁶ Nonetheless, patients with chronic asthma and airways remodeling, bronchiectasis, cystic fibrosis, chest wall disease, or interstitial lung disease may be appropriate candidates.⁴⁷ Pulmonary rehabilitation is the standard of care before and after lung transplantation and lung volume reduction surgery. On the basis of these accepted indications, pulmonary rehabilitation should also be useful to recondition patients for other major surgical procedures.

There are two primary exclusion criteria for pulmonary rehabilitation:

1. An associated condition that might interfere with the rehabilitative process. Examples include disabling arthritis and severe neurologic, cognitive, or psychiatric disease.
2. A comorbid condition that might place the patient at undue risk during exercise training. Examples include severe pulmonary hypertension or unstable cardiovascular disease.

It should be noted that many patients with pulmonary hypertension have safely (and successfully) participated in pulmonary rehabilitation programs, often while awaiting lung transplantation. The exercise training component has to be modified in this situation and patients require close monitoring. In addition, poor motivation is a relative contraindication to pulmonary rehabilitation. However, the level of motivation might change during therapy, especially if patients perceive demonstrable benefit from the sessions.

SMOKING CESSATION

Cigarette smoking is the cause of COPD in more than 90% of affected patients. Furthermore, there is no doubt that smoking cessation is the single most important therapy that can retard the progression of airflow limitation and positively influence survival. The various pharmacologic and behavior modification techniques that are available to assist persons to stop smoking are reviewed in Chapter 46. Although controversy still exists, active cigarette smokers are reasonable candidates for pulmonary rehabilitation provided smoking cessation interventions become an important component of the process. Indeed, frequent contact and reinforcement during the rehabilitation program can influence a patient to adopt a proactive role in cessation.

COMPONENTS OF A COMPREHENSIVE PULMONARY REHABILITATION PROGRAM

EXERCISE TRAINING

Exercise training, including upper and lower extremity endurance training and strength training, is an essential component of comprehensive pulmonary rehabilitation. This follows the current knowledge that the peripheral muscles in patients with chronic lung disease are not only wasted but also appear to have alterations in fiber type distribution and decreased metabolic capacity.^{47a} Exercise training improves endurance, increases the level of functioning, aids in performance of activities of daily living, helps reduce systemic blood pressure, improves lipid profiles, tends to counteract depression, reduces anxiety associated with dyspnea-producing activities, and facilitates sleep.

Exercise training for individuals with chronic lung disease, similar to that in healthy individuals, is based on general principles of intensity (higher levels of training produce more results), specificity (only those muscles trained show an effect), and reversibility (cessation of regular exercise training leads to loss of training effect).⁴⁸

Ventilatory or gas-exchange limitations are common in advanced chronic lung disease and limit the intensity of exercise training. However, exercise capacity in many patients is also limited by peripheral muscle and cardiovascular deconditioning, with an early onset of anaerobic metabolism and the production of lactic acidosis during exercise. Peripheral muscle dysfunction is responsive to the exercise training intervention. Many respiratory patients are capable of exercising for prolonged periods of time at levels close to capacity,⁴⁹ and the higher level of exercise training results in greater improvement in exercise performance.³⁸ The demonstrated reduction in ventilation and lactate levels at identical submaximal work rates²¹ following high-intensity exercise training strongly suggests that a training effect is attainable in many patients with advanced lung disease. A dose-related increase in oxidative enzymes in the peripheral muscles accompanies these physiologic adaptations to training.⁴³ A reduction in lactic acid production has been demonstrated to be associated with improvement in oxidative capacity of the peripheral muscles.⁵⁰

Most pulmonary rehabilitation programs emphasize endurance training of the lower extremities, often advocating sustained exercise for about 20 to 30 minutes two to five times a week. This may include exercise on a stationary cycle ergometer or motorized treadmill, climbing stairs, or walking on a flat surface such as a corridor or auditorium. Training is usually performed at levels at or greater than 50% or 60% of the maximal work rate. For those unable to maintain this intensity for the recommended duration, interval training, consisting of 2 to 3 minutes of high-intensity training (60% to 80% maximal exercise capacity), alternating with equal periods of rest, has similar results with less dyspnea.^{51,52} Optimization of bronchodilator therapy is desirable because it will allow patients to exercise at higher intensities. Similarly, supplemental oxygen therapy for hypoxemic patients, in addition to increasing safety, will allow patients to train at higher work rates.

Oxygen supplementation may even promote exercise training at higher intensities in nonhypoxemic COPD patients,⁵³ but further studies will be necessary to confirm that this approach is effective. If patients cannot achieve high work rates during exercise training, lower work rates have also been demonstrated to produce positive outcomes.⁵⁴

Although the strength of the upper extremity muscles is relatively preserved compared with that of the lower extremities in COPD,⁵⁵ the former are important to many activities of daily living. The use of upper extremity muscles is often associated with considerable dyspnea, probably because the arm muscles are also accessory muscles of respiration. Endurance training of the upper extremities is thus an important component of pulmonary rehabilitation. Its effectiveness has recently been demonstrated in a randomized clinical trial.⁵⁶ Training can be accomplished using supported arm exercises, such as with arm ergometry, or unsupported arm exercises, such as by lifting free weights or dowels or by stretching elastic bands.⁵⁷

Because peripheral muscle weakness and/or atrophy contributes to exercise limitation in patients with lung disease,⁵⁸ strength training is a rational component of exercise training during pulmonary rehabilitation.⁵⁹ Training in weight-lifting exercises alone, involving the upper and lower extremities, increases muscle strength and endurance performance on a cycle ergometer.⁶⁰ In the current practice of pulmonary rehabilitation, strength training is usually added to standard aerobic training. This combination increases muscle strength and mass, but its additive effect on health status has not been proved.⁶¹

The total duration of exercise training in pulmonary rehabilitation should reflect the patient's underlying respiratory disease, his or her level of physical and cardiovascular conditioning, and the progress made during the exercise training sessions. The GOLD guidelines¹⁶ report that the optimum length of exercise training has not been determined in randomized, controlled trials but suggests there is evidence that programs of longer duration provide greater benefit. Ideally, the optimal length of an exercise training program should depend on whether the patient continues to progress toward goals. However, in reality, the program length is generally set by resources, reimbursement, and continued patient motivation. Longer programs may provide more sustained benefits in outcomes.⁶²

Exercise training is typically given in the pulmonary rehabilitation facility under supervision. Generally, this is supplemented with patient-specific instructions for additional exercise training at home or in the community. Early incorporation of home exercise into the routine of daily life may promote long-term adherence with the exercise prescription. Carrying this concept one step further, a randomized trial demonstrated that, after 4 weeks of standardized education, 8 weeks of exercise training *in the home* was as effective in its primary outcome as 8 weeks of supervised training in the pulmonary rehabilitation center.⁶³ The primary outcome in this study was questionnaire-rated dyspnea at 1 year following rehabilitation. Similar improvements were noted in exercise capacity, although the mean changes in the 6-minute walk distance were well below the established minimum clinically important difference of 54 m. Of importance, there were no significant differences in adverse events in the two groups, and the treating physi-

cians and the study steering committee did not identify any serious adverse events attributable to the exercise training. It remains to be determined whether this home exercise approach to pulmonary rehabilitation will become a practical alternative to the traditional approach.

EDUCATION

Education is an important component of pulmonary rehabilitation programs, and its incorporation alongside exercise training provides a good setting to promote the health behavior change necessary to optimize disease control. Educational needs are determined as part of the initial patient assessment and then are reassessed over the course of the program. Education provides important information to the patient and family about the disease process, its comorbidity, and its treatment. This information encourages active participation in health care, thereby promoting adherence to therapy and important self-management skills.^{64,65} Education also helps the patient and family find ways to cope with chronic illness and its comorbidities.⁶⁶ Some standard educational topics are listed in [Table 105-1](#). In pulmonary rehabilitation, education is usually provided both in small-group settings and in a one-to-one format.

The educational process includes the promotion of a healthy lifestyle, the incorporation of adaptive techniques (such as self-pacing) into the home setting, and the promotion of long-term adherence with the postrehabilitative instructions. Education about self-management is an essential component of pulmonary rehabilitation. It emphasizes "learning through doing," enhances patient self-confidence, and encourages a "take-charge" attitude (in collaboration with the health care providers) toward managing the disease.¹⁷ Some strategies in collaborative self-management include interventions for smoking cessation, encouragement of regular exercise at home, incorporation of increased levels of physical activity into the home setting, and early recognition and treatment of respiratory exacerbations. The development of a patient-specific, collaborative self-management plan for COPD exacerbations is an important goal of pulmonary rehabilitation; this includes education about the symptoms and signs associated with

exacerbations to foster early recognition followed by the implementation of an action plan, which often includes using filled prescriptions for a short course of systemic steroids and an antibiotic. Ongoing collaboration among the patient and the medical team members is the key to effective self-management. Advance directive discussions are also an important component of pulmonary rehabilitation (see later).⁶⁷⁻⁶⁹

Because education is a component of virtually all pulmonary rehabilitation programs, there are few studies evaluating its individual contribution to the overall effectiveness of the comprehensive program. However, self-management strategies applied to the home setting have been shown to be effective in improving health status and reducing utilization of medical resources.²⁹

PSYCHOSOCIAL TRAINING AND SUPPORT

Psychosocial problems, such as anxiety, depression, problems coping, and decreased self-efficacy, contribute to the burden of advanced respiratory disease.⁷⁰ Psychosocial and behavioral interventions vary widely among comprehensive pulmonary rehabilitation programs but often involve educational sessions or support groups, focusing on areas such as coping strategies or stress management techniques. Techniques of progressive muscle relaxation, stress reduction, and panic control may reduce not only anxiety but dyspnea as well.⁷¹ Educational efforts may also improve coping skills. Participation by family members or friends in pulmonary rehabilitation support groups is encouraged. Informal discussions of the common symptoms and concerns of patients with chronic lung disease may provide emotional support to patients and their families. Because of these interventions, it should come as no surprise that a randomized clinical trial has demonstrated that comprehensive pulmonary rehabilitation can decrease psychosocial morbidity in patients with severe COPD even when no specific psychological intervention is provided.⁷² Individuals with substantial psychiatric disease should, of course, be referred for appropriate professional care.

NUTRITIONAL SUPPORT

Nutritional depletion, including abnormalities in body composition such as decreased lean body mass, is present in 20% to 35% of patients with stable COPD.^{73,74} Depletions in lean body mass undoubtedly contribute to the morbidity of patients with chronic respiratory disease by leading to decreased respiratory muscle strength,⁷⁵ handgrip strength,⁷⁶ exercise tolerance,^{77,78} and health status.⁷⁹ Nutritional depletion and alteration in body composition are also significant predictors of the mortality of COPD, independent of FEV₁.^{8,9,80} Because of this, nutritional intervention is a recommended component of comprehensive pulmonary rehabilitation.

However, the benefit from simple nutritional supplementation to underweight patients with chronic lung disease has not been substantial, with one meta-analysis of nutritional intervention for COPD reporting only a 1.65-kg increase in weight following intervention.⁸¹ In view of these disappointing results with calorie supplementation alone,

consideration is being given to hormonal supplementation with anabolic steroids.⁸² This has led to increases in weight, lean body mass, respiratory muscle strength, and arm and thigh muscle circumference.⁸³ In addition, one study has demonstrated that the combination of testosterone and weight training in men with COPD and low testosterone levels leads to greater increases in muscle mass and strength than either alone.⁸⁴ Whether these preliminary findings in this select group can be applied with safety and efficacy to a more generalized population remains unknown. The Joint ACCP/AACVPR Guidelines on Pulmonary Rehabilitation² do not recommend routine use of anabolic steroids for COPD patients.

BREATHING TRAINING, INSPIRATORY MUSCLE TRAINING, AND CHEST PHYSICAL THERAPY

These modalities have been part of pulmonary rehabilitation over the years, but conclusive evidence supporting their effectiveness in pulmonary rehabilitation is for the most part lacking. Breathing training is aimed at controlling the respiratory rate and breathing pattern, with a goal of decreasing air trapping. *Pursed-lip breathing* takes place when the patient inhales through the nose and exhales over 4 and 6 seconds through lips pursed in a whistling/kissing position. This technique facilitates the recruitment of abdominal muscles during exhalation and has a favorable effect on the breathing pattern, thereby increasing tidal volume and reducing end-expiratory lung volumes. The result is less hypoxemia and decreased dyspnea. In selected patients, pursed-lip breathing has also been shown to reduce the oxygen cost of breathing.⁸⁵ Patients with COPD can usually be readily trained in pursed-lip breathing; in fact, they often spontaneously adopt this breathing pattern when dyspneic. *Breathing while bending forward* has been shown to decrease dyspnea in some patients with severe COPD, both at rest and during exercise. Similar improvements can be achieved by breathing in the supine and Trendelenburg positions. The best explanation for the reduction in dyspnea is that the increased abdominal pressure caused by bending over stretches the diaphragm, moving it into a better contracting position and leading to improved diaphragmatic function. *Diaphragmatic breathing* has not been shown to be beneficial; in fact, this technique may actually decrease breathing efficiency.⁸⁵

The rationale behind inspiratory muscle training is that COPD patients have weak inspiratory muscles and that training them may improve outcomes. The Joint ACCP/AACVPR Evidence-Based Clinical Practice Guidelines reviewed the relatively numerous studies on inspiratory muscle training and concluded that this treatment increases inspiratory muscle strength, increases exercise performance, and decreases dyspnea. Their recommendation is to consider inspiratory muscle training in selected COPD patients with decreased inspiratory muscle strength and breathlessness despite optimal medical therapy.²

Chest physical therapy is used in an attempt to remove airway secretions. The techniques include postural drainage, chest percussion and vibration, and directed cough. Postural drainage uses gravity to help drain the individual lung segments. Chest percussion should be performed with

care in patients with osteoporosis or bone problems. Cough would be an effective technique for removing excess mucus from the larger airways; unfortunately, patients with COPD have impaired cough mechanisms (maximum expiratory flow is reduced, ciliary beat is impaired), and the mucus itself has altered viscoelastic properties. Because spasms of coughing may lead to dyspnea, fatigue, and worsened obstruction, directed cough might be helpful by enhancing the beneficial effect and preventing the untoward ones. With directed coughs, patients are instructed to inhale deeply, hold their breath for a few seconds, and then cough two or three times with the mouth open. They are also instructed to compress the upper abdomen to assist in the cough. These techniques are probably useful in selected patients with difficulty mobilizing secretions.

VACCINATION

The causes of exacerbations of COPD are poorly understood and probably multifactorial. Both influenza virus and *Streptococcus pneumoniae* may play a role, and there is no doubt that, with either of these infections, patients with chronic lung disease are at increased risk for serious complications, including death.⁸⁶ One of the national health objectives in the United States has been to increase influenza and pneumococcal vaccination levels to higher than 60% in persons at high risk for complications and for everyone 65 years of age or older.⁸⁷ As stated, this includes all patients with COPD and other forms of chronic lung disease, regardless of age. Because the influenza vaccine is type specific and serotypes are constantly changing, vaccination must be repeated every year, preferably at the beginning of the season in the fall. In contrast, the pneumococcal vaccine is polyvalent and its benefits should last a lifetime.⁸⁸ One of the responsibilities of a rehabilitation program is to educate enrollees about the importance of vaccination against influenza and pneumococcal infections and to ensure that it is carried out and (for influenza) repeated annually.

OXYGEN ASSESSMENT AND THERAPY

Background

Although not in itself a unique component of pulmonary rehabilitation, testing for oxygen needs and/or adjusting the oxygen to achieve its full benefits is part of all rehabilitation programs. Two landmark studies clearly showed improved survival in patients with COPD and hypoxemia (arterial oxygen pressure $PO_2 < 55$ mm Hg) who breathed supplementary oxygen at night compared with those who received no supplemental oxygen; there was even better survival in those who breathed oxygen for longer periods through the aid of an ambulatory delivery system.^{89,90} Contemporary guidelines for prescribing home oxygen for patients with COPD, based in part on these trials, are shown in Table 105-2. The chief criterion is significant hypoxemia, defined as an arterial PO_2 of 55 mm Hg or less for 3 weeks or more when the patient is in a clinically stable state (i.e., has been free from exacerbation of bronchitis, heart failure, or other intercurrent complications). Additional criteria were also used in the North American multicenter trial to

Table 105-2 Guidelines for Prescribing Home Oxygen for Advanced Chronic Obstructive Pulmonary Disease

PATIENT SELECTION CRITERIA

Accepted Indications

Patients with resting PaO_2 consistently 55 mm Hg or less
 Patients with resting PaO_2 consistently 55–59 mm Hg *plus* cor pulmonale clinically diagnosed and/or hematocrit >55% and stable course of disease on optimal therapy
 Patients with nocturnal hypoxemia (i.e., $PaO_2 < 55$ mm Hg on multiple occasions or hematocrit >55% or clinical evidence of pulmonary hypertension)

Possible Indications

Normoxic patients in whom oxygen has been shown to reduce dyspnea and substantially increase exercise capability
 For supplementation during exercise training

OXYGEN DOSE

Continuous flow by double or single nasal cannulas (see text) or by demand system with demonstration of adequate oxygen saturation
 Lowest flow to increase PaO_2 to 60–65 mm Hg or oxygen saturation to 90–94%
 Increase baseline flow by 1 L/min during exercise and sleep. Consider higher flows if patient traveling by air

PaO_2 , arterial oxygen pressure.

Adapted from Celli BR, MacNee W, ATS/ERS Task Force, et al: Standards for the diagnosis and treatment of patients with COPD: a summary of the ATS/ERS position paper. *Eur Respir J* 23:932–946, 2004.

enroll stable patients with COPD whose arterial PO_2 values were between 55 and 59 mm Hg.⁸⁹ They included evidence of pulmonary hypertension as judged by radiographic abnormalities (an enlarged pulmonary outflow tract); electrocardiographic findings of elevated right-sided intracardiac pressures (P waves in standard leads II, III, and aVF > 2-mm amplitude); clinical evidence of cor pulmonale with heart failure; or secondary polycythemia from chronic hypoxemia. Patients with COPD who have echocardiographic evidence of right ventricular hypertrophy and/or pulmonary hypertension also qualify.

Dosage

The therapeutic goal of administering supplementary oxygen is to raise arterial PO_2 to 60 to 65 mm Hg or, alternatively, to reach an oxygen saturation of 90% to 94%. The results of the *Nocturnal Oxygen Therapy Trial* (NOTT)⁸⁹ established that the great majority of patients with advanced COPD and hypoxemia achieve this goal with oxygen delivered by nasal cannula at 1 to 2 L/min. Less than 10% of the patients require 3 L/min or more while at rest. Additional results obtained during the conduct of the trial indicate that additional oxygen of 1 L/min was required during the stress of exercise and while sleeping; those extra needs are undoubtedly caused by the increased metabolic demands of exercise and the modest degree of hypoventilation and/or worsening of gas exchange seen during sleep.

Thus, if the baseline flow of oxygen is 2 L/min with patients at rest, the flow rate should be turned up to 3 L/min when they are exercising or sleeping. Periodic monitoring of oxygenation is essential to determine who should receive supplementary oxygen in the first place; moreover, in those who are being treated, monitoring is used to evaluate

whether therapeutic goals are being met or exceeded. Two techniques are available: arterial puncture to measure PaO₂ and pulse oximetry to measure oxygen saturation. The latter is being increasingly used given the convenience and improved accuracy of the newer oximeters.

Delivery Systems

The oxygen delivery systems available for home use are as follows: compressed gas in high-pressure cylinders; liquid gas in lightweight canisters; and stationary oxygen concentrators. Large compressed gas cylinders are fixed in place, but patients can move short distances while using long (50-ft) tubing; smaller cylinders can be attached to wheelchairs or installed in automobiles to allow journeys out of the home. Ambulatory patients are best served with a small portable, liquid system, which is the only practicable way to deliver oxygen to someone who is working or active. Liquid gas-containing canisters and portable oxygen concentrators are constantly being improved to reduce weight and to increase duration of use. Because the goal of pulmonary rehabilitation is to restore the patients' functional capacity to its optimal level and exercise is a fundamental part of pulmonary rehabilitation, every effort must be made to provide hypoxemic patients with portable devices that help achieve these goals.

Oxygen as an Adjunct to Pulmonary Rehabilitation Exercise Training

In addition to life-prolonging effects, supplemental oxygen therapy increases exercise capacity in hypoxemic⁹¹ and even nonhypoxemic⁹² COPD patients. Part of this beneficial effect is probably mediated through a reduction in carotid body respiratory drive, resulting in a lower respiratory rate and, consequently, less dynamic hyperinflation. Because supplemental oxygen increases exercise capacity in COPD patients, it may enhance outcomes in pulmonary rehabilitation by allowing patients to exercise and train at higher intensities. Oxygen therapy for individuals with exercise-induced hypoxemia is a standard of care in the United States, but the role of oxygen therapy for nonhypoxemic patients as a potential exercise-enhancer is not well established. To date, a few clinical trials have demonstrated that supplemental oxygen (or oxygen plus helium) during pulmonary rehabilitation exercise training in nonhypoxemic patients with COPD may allow for exercise training at higher intensities and greater short-term improvement from the intervention.^{93,94} Further research is necessary in this area.

LONG-TERM ADHERENCE

Although the short-term effects of pulmonary rehabilitation in multiple outcome areas are firmly established, the long-term effectiveness of this therapy is often disappointing. In controlled trials of pulmonary rehabilitation, gains in exercise performance and health status obtained after 6 to 8 weeks of therapy essentially disappear by 18 to 24 months.²⁵ However, it seems illogical to expect that a therapy that is only applied for 6 to 8 weeks could substantially modify the natural course of the disease. In all likelihood, two factors are mainly responsible for this drop-off in effectiveness: (1) exacerbations of underlying lung disease,

leading to prolonged symptoms and resuming a more sedentary lifestyle and (2) a gradual decline in adherence with the postrehabilitation exercise prescription. With these factors in mind, the pulmonary rehabilitation program must include strategies to promote long-term adherence. One approach is to incorporate the principles of pulmonary rehabilitation, including exercise training, more actively into the home setting. This is supported by studies of home-based programs, which suggest that gains made in this setting may be longer lasting⁹⁵ than those of hospital-based programs. Promoting regular walking seems to help prolong effectiveness in some outcome areas.⁹⁶ Although regularly scheduled repeated pulmonary rehabilitation sessions do not give additional prolonged benefit,⁹⁷ giving a "booster shot" of pulmonary rehabilitation following an exacerbation, by emphasizing short periods of supervised exercise training to return the patient to baseline performance, appears to be a reasonable intervention in selected cases. Longer-duration pulmonary rehabilitation seems to confer longer-lasting effectiveness.⁶²

PULMONARY REHABILITATION AND THE INTEGRATED CARE OF THE RESPIRATORY PATIENT

The *American Thoracic Society/European Respiratory Society* (ATS/ERS) guidelines define pulmonary rehabilitation as "a spectrum of intervention strategies integrated into the life-long management of patients with chronic respiratory disease and involves a dynamic, active collaboration among the patient, family and healthcare providers."¹ Depending on the specific needs of the individual patient, this care might include smoking-cessation counseling and therapy, activity promotion, education about a healthy lifestyle, vaccinations, the incorporation of regular exercise training into the individual's lifestyle, optimization of pharmacology, an exacerbation prevention strategy, a collaborative management plan for the early recognition and treatment of exacerbations, and discussion of advance directives. These interventions can be conveniently bundled into a comprehensive outpatient or inpatient pulmonary rehabilitation program administered by a multidisciplinary staff. However, if pulmonary rehabilitation is not available or feasible for a particular patient, the onus of this patient-centered comprehensive management rests on the health care provider. Unfortunately, our current acute care health model is poorly suited for this type of management. Another approach—which has not yet been implemented to any significant degree—is the concept of *integrated care*.¹⁷ Integrated care, as it applies to individuals with respiratory disease, has been described as "a system-wide, multidisciplinary, collaborative approach that is individualized to the specific needs of the patient. This approach stresses comprehensive assessment, self-management education, agreement on an individually tailored care plan, and communication among health care professionals, patients, and families/caregivers."^{17,98} An integrated care approach would be particularly useful during COPD exacerbations, when there is an abrupt deterioration in the patient's condition and a far greater likelihood of increased health care utilization. Some data suggest that an integrated care approach in this setting reduces health care costs.⁹⁹

PROMOTING PHYSICAL ACTIVITY IN THE PATIENT WITH CHRONIC RESPIRATORY DISEASE

Daily activity energy expenditure is an important predictor of mortality in healthy community-dwelling older adults,¹⁰⁰ and patients with COPD are more sedentary than age-matched healthy individuals.¹⁰¹ Hypoxemic COPD patients are generally very sedentary and, disappointingly, supplemental oxygen is not particularly effective in reversing this maladaptive behavior.¹⁰² Because decreased physical activity in COPD patients appears to be related to increased health care utilization and mortality,^{103,104} an important goal of pulmonary rehabilitation is to promote increased physical activity in the home and community settings. Although pulmonary rehabilitation unequivocally increases exercise capacity, it is less clear whether the increase in exercise capacity is translated into increased physical activity outside the pulmonary rehabilitation environment. Clinical trials incorporating direct measurements of physical activity using motion detectors (accelerometers worn at the waist or on the leg) have demonstrated that pulmonary rehabilitation does indeed increase physical activity.³⁵⁻³⁷

PROGRAM ORGANIZATION

The pulmonary rehabilitation program needs a coordinator to organize the various components into a functioning unit. The coordinator develops the integrated program and monitors its progress and function. The program should have resources available to teach and supervise respiratory therapy (oxygen, use of inhalers, nebulizers); physical therapy (breathing techniques, chest physical therapy, postural drainage); exercise conditioning (upper and lower extremities); and activities of daily living (work simplification, energy conservation). Also desirable are services to evaluate and advise on nutritional, psychological, and vocational needs.

Whether to have an inpatient or an outpatient program depends on the methods of reimbursement, patient population, available personnel, and institutional policy. The ideal system is one that provides an in-hospital component for patients who may benefit from the program while recovering from acute exacerbations and an outpatient component (including home therapy) that could complete the program started in the hospital. This program ensures good continuity of care.

OUTCOME ASSESSMENT

Outcome assessment can be defined as the assessment of the “consequences” of an intervention. As stated earlier, pulmonary rehabilitation does not improve physiologic pulmonary function. However, exercise training in rehabilitation increases the content of oxidative enzymes in the trained muscles, accompanied by a beneficial delay in the generation of lactate (a marker of muscle performance). This results in improved exercise performance and reduced dyspnea and it may be responsible, at least in part, for improved functional capacity. Therefore, even though pul-

Table 105-3 Examples of Outcome Assessment for Pulmonary Rehabilitation

Measurement	Scales/Tests
Exertional dyspnea	Borg scale or visual analogue scale during exercise testing
Dyspnea with daily activities	Modified Medical Research Council (MRC) questionnaire, Baseline and Transitional Dyspnea Indexes (BDI/TDI), San Diego Shortness of Breath Questionnaire (SOBQ)
Functional exercise capacity	Six-minute walk test Incremental and endurance shuttle walk tests
Laboratory measures of exercise performance	Incremental cardiopulmonary exercise testing Endurance testing at constant work rate
Health status	Chronic Respiratory Disease Questionnaire (CRQ), St. George's Respiratory Questionnaire (SGRQ), Medical Outcomes Study Short Form-36 (SF-36)
Functional performance	Pulmonary Functional Status Scale (PFSS) Pulmonary Function Status and Dyspnea Questionnaire (PFSDQ)
Nutritional status/body composition	Body mass index (BMI) Body composition using bioelectrical impedance or dual-energy x-ray absorption (DEXA)
Psychological variables	Measurement of anxiety and depression using the Hospital Anxiety and Depression (HAD) questionnaire

monary rehabilitation does not improve lung function, it reduces the disability and handicap of the patient.

Outcome assessment for pulmonary rehabilitation encompasses three areas: (1) a general audit of the effectiveness of the global pulmonary rehabilitation program and its components; (2) evaluation of individual patient response to the intervention; and (3) assessment of the effect of pulmonary rehabilitation on society, especially with respect to its effect on health care utilization and its cost-effectiveness. Some commonly used outcome measures are listed in [Table 105-3](#).

Evaluating the effectiveness of the pulmonary rehabilitation program for its patient population as a whole is important in continuous quality assessment. Evaluation can be made of several of its components, especially in the measurements of dyspnea, exercise performance, and health status. Dyspnea evaluation falls into two categories: measurement of exertional dyspnea during standardized exercise testing and measurement of breathlessness by questionnaire. Exertional dyspnea is usually rated using a Borg scale¹⁰⁵ or a visual analogue scale. Measurement of dyspnea by questionnaire usually assesses the dyspnea associated with daily activities or the way in which exertional dyspnea limits activities.¹⁰⁶ Exercise performance can be measured in the laboratory using protocols involving incremental treadmill or stationary bicycle exercise. However, field tests of exercise performance, such as the 6-minute walk test or the shuttle walk test, are more commonly performed. The 6-minute test is easy to perform, relates well to functional status, and is responsive to the pulmonary rehabilitation intervention. As stated earlier, the 6-minute walk

test is a better predictor of mortality in patients with COPD than is lung function. For the shuttle walk test,¹⁰⁷ the patient is instructed to walk around a 10-meter course at gradually increasing speeds. Speed is determined by an auditory beeping signal that sets the pace. The test is terminated when the patient cannot complete the course in time, usually because of breathlessness. Total distance traveled is the variable assessed. Health status is often assessed using respiratory-specific questionnaires, such as the *Chronic Respiratory Disease Questionnaire* (CRQ)¹⁰⁸ or the *St. George's Respiratory Questionnaire* (SGRQ).¹⁰⁹ Some pulmonary rehabilitation programs may also use a generic instrument, such as the *Medical Outcomes Study Short Form-36* (SF-36),¹¹⁰ to complement information from the respiratory-specific questionnaires. Assessment in the areas of nutrition/body composition, educational goal achievement, and psychosocial variables (e.g., anxiety, depression, coping skills) is also possible. In sum, a pulmonary rehabilitation program can be judged on its ability to improve patient function by these component measures.

In the evaluation of the response to therapy of an *individual* patient, exercise tests such as the timed walk, a questionnaire assessment of dyspnea, or measurements of functional status or health status may provide some useful information. However, to date, these outcome measures, which have become routine for program assessment, have not been extensively validated for individual patient assessment. Traditional one-on-one clinical assessment remains necessary for the individual patient.

Finally, the pulmonary rehabilitation can be evaluated for its effect on society, especially with respect to its effect on health care utilization and its cost-effectiveness. Outcome assessment in health care utilization or cost-effectiveness generally requires participation of several centers in a multicenter study to accrue the necessary number of subjects for this type of analysis.

RECENT ADJUNCTS

Several adjuncts may prove to be beneficial in patients with severe disability from chronic respiratory disease. *Noninvasive positive-pressure ventilation* (NPPV; see Chapter 102), through its effect in helping unload the respiratory muscles, improves breathlessness and exercise endurance in COPD.¹¹¹⁻¹¹³ When NPPV is added to pulmonary rehabilitation in patients with hypercapnic COPD and used at home, there is an improvement in dyspnea, health status score, exercise endurance, arterial blood gases, and lung function compared with rehabilitation alone. However, it has failed to demonstrate a decrease in exacerbations and mortality.¹¹⁴ The use of proportional assist ventilation in pulmonary rehabilitation in patients without hypercapnia had no appreciable added benefits in mild COPD.¹¹⁵ However, in patients with more severe lung disease, this form of therapy allowed the patient to exercise at a higher intensity, resulting in the achievement of a greater maximum exercise capacity.¹¹⁶ The Joint ACCP/AACVPR Evidence-Based Clinical Practice Guidelines stated that NPPV does confer a postrehabilitation benefit in patients with severe airflow limitation.² Similarly, the application of electrical stimulation combined with active limb mobilization in COPD

patients on mechanical ventilation or with other patients with severe disability improves muscle strength and provides other patient-centered outcomes.¹¹⁷⁻¹²⁰ Finally, the inhalation of less-dense, oxygen-enhanced gas mixtures, such as 72% helium/28% oxygen, can improve exercise performance in patients with severe COPD.¹²¹ These techniques remain fruitful topics for research.¹²²

The potential benefits of palliative care at home, at least in patients with COPD, are beginning to be studied, but initial results in a small randomized trial¹²³ indicate that a significant number of barriers exist before recommending this intervention widely for patients with severe, debilitating COPD. Research in this area is of utmost importance as the aging population and the impact of noninfectious, noncommunicable diseases become the most frequent cause of morbidity and death in the world.¹²⁴

ADVANCE CARE PLANNING

Participation in a pulmonary rehabilitation program provides an excellent environment to address discussions of advance care planning.⁶⁸ As part of the educational component of pulmonary rehabilitation, information can be provided about designating a health care proxy (also known as durable power of attorney for health care). Pulmonary rehabilitation provides a unique opportunity to provide family members with a clear sense of the individual patient's goals for treatment and preferences regarding the use of life-sustaining treatments, such as mechanical ventilation, cardiopulmonary resuscitation, feeding tubes, and dialysis. Advance care planning education in the context of a pulmonary rehabilitation program is generally well accepted.⁶⁹

Key Points

- Pulmonary rehabilitation is a multidisciplinary, patient-centered approach to the treatment of patients with chronic respiratory disease.
- Although pulmonary rehabilitation has no direct effect on lung function, it nonetheless produces substantial improvements in dyspnea, exercise performance, and quality of life and reduces health care utilization.
- Whereas most patients referred for pulmonary rehabilitation have COPD, this therapy can help patients with other respiratory diseases.
- Important components of pulmonary rehabilitation include education, exercise training, nutritional therapy, psychosocial support, and advance care planning.
- Exercise training is the cornerstone of pulmonary rehabilitation; high-intensity, low-intensity, and strength training of upper and lower extremities are all utilized.
- Promotion of physical activity in the home and community setting is an important goal of pulmonary rehabilitation.
- Optimization of pharmacologic therapy and supplemental oxygen (when indicated) may allow the patient to exercise at higher intensity and thereby achieve greater increases in exercise performance.

RETRANSPLANTATION**FUTURE DIRECTIONS****INTRODUCTION**

Human lung transplantation was first attempted in 1963, but it was not until nearly 2 decades later that extended survival was achieved. Further refinements in patient selection, surgical technique, immunosuppression, and postoperative care have since facilitated the successful application of lung transplantation to a wide variety of advanced disorders of the airways, lung parenchyma, and pulmonary vasculature. The field has realized dramatic growth, with more than 47,000 procedures performed worldwide to date with approximately 3700 now performed annually.¹ Nonetheless, serious problems persist that limit the utility of this procedure. The donor pool remains insufficient to meet the demands of the many desperately ill patients awaiting transplantation. Immunosuppressive therapy is associated with a number of troubling side effects, most notably a significant risk of infection and malignancy. Despite the use of immunosuppressive agents, rejection develops frequently and continually threatens organ function. Though lung transplantation offers the prospect of improved functional status and quality of life, long-term survival remains an elusive goal, with only half of recipients living beyond 5 years. In order to optimize outcomes in the face of these shortcomings, judicious selection of candidates is essential and care of recipients must be rendered in a meticulous and vigilant fashion by clinicians familiar with the hazards of posttransplant life.

INDICATIONS AND CANDIDATE SELECTION

Lung transplantation is a therapeutic option for a broad spectrum of chronic debilitating pulmonary disorders of the airways, parenchyma, and vasculature. Leading indications include *chronic obstructive pulmonary disease* (COPD;

28% of cases), *idiopathic pulmonary fibrosis* (IPF; 29% of cases), and *cystic fibrosis* (CF; 15% of cases).¹ Other less common indications include emphysema due to α_1 -antitrypsin deficiency, sarcoidosis, non-CF bronchiectasis, and lymphangioleiomyomatosis. Once a common indication for transplantation, idiopathic pulmonary arterial hypertension now accounts for less than 3% of procedures, reflecting major advances in the medical management of these patients. Transplantation of patients with lung involvement due to collagen vascular disease remains controversial due to concerns that extrapulmonary manifestations of the systemic disease could compromise the posttransplant course. In particular, the esophageal dysmotility and reflux that frequently characterize scleroderma could increase the risk of aspiration and accelerated graft loss. The demonstration that posttransplantation survival of scleroderma patients is comparable with other patient populations provides some reassurance that carefully selected patients can benefit from this procedure.^{2,3} Use of lung transplantation for locally advanced bronchioloalveolar carcinoma (now referred to as *adenocarcinoma in situ*) has largely been abandoned due to an unacceptably high rate of cancer recurrence.⁴

Many transplant centers define an age cutoff for transplant eligibility, typically 65–70 years. In support of this policy, advanced recipient age has been consistently identified as a risk factor for increased posttransplant mortality.¹ Nonetheless, there has been a growing trend to expand the age range on the basis of the argument that “functional” rather than chronologic age should be considered. This trend has been most pronounced in the United States, where patients 65 years and older accounted for 27% of transplant recipients in 2011 compared with 3% in 2001.⁵ Two recent single-center case series involving 50 and 78 patients, respectively, who were 65 years or older found no difference in 1-year and 3-year posttransplant survival rates compared with younger cohorts.^{6,7} However, the *United Network for Organ Sharing* (UNOS) database of U.S.

transplants documents a 10-year survival rate among recipients 65 and older of only 13% compared with 23% for those 50 to 64 years and 38% for those younger than 50 years.⁸

There are surprisingly few remaining absolute contraindications to lung transplantation. There is general consensus that the following contraindicate transplantation: (1) recent malignancy (other than nonmelanoma skin cancer); (2) active infection with hepatitis B or C virus associated with histologic evidence of significant liver damage; (3) active or recent cigarette smoking, drug abuse, or alcohol abuse; (4) severe psychiatric illness; (5) repeated noncompliance with medical care; and (6) absence of a consistent and reliable social support network.⁹ Infection with *human immunodeficiency virus* (HIV) is still viewed by most centers as an absolute contraindication, but promising results with liver, kidney, and heart transplantation in HIV-positive recipients, as well as a recent case report of successful lung transplantation, may soon remove this barrier.¹⁰

The presence of significant extrapulmonary vital organ dysfunction precludes isolated lung transplantation, but multiorgan procedures such as heart-lung or lung-liver can be considered in highly selected patients. Both obesity and underweight nutritional status increase the risk of posttransplant mortality, but cutoffs for exclusion of candidates vary among centers.¹¹ The risk posed by other chronic medical conditions such as diabetes mellitus, osteoporosis, gastroesophageal reflux, and coronary artery disease must be assessed individually on the basis of severity of disease, presence of end-organ damage, and ease of control with standard therapies.

Prior pleurodesis is associated with an increased risk of intraoperative bleeding, particularly when cardiopulmonary bypass is used, but is not a contraindication to transplantation in experienced surgical hands. Pleural thickening associated with aspergillomas similarly complicates anatomic dissection and explantation of the native lung and carries the additional risk of soiling the pleural space with fungal organisms.

Among candidates with CF, colonization with certain species comprising the *Burkholderia cepacia* complex, in particular *Burkholderia cenocepacia* (previously known as genomovar III), is considered a strong contraindication by the majority of centers, owing to the demonstrated propensity of this organism to cause lethal posttransplant infections.^{12,13} In contrast, the presence of pan-resistant *Pseudomonas aeruginosa* in this patient population is associated with acceptable outcomes and should not be viewed as a contraindication.¹⁴

Transplantation of patients on mechanical ventilation is associated with increased short-term posttransplant mortality though it does not appear to affect outcomes beyond the first year.¹ Although transplantation of these patients was previously discouraged, the new lung allocation system in the United States has prompted reconsideration of this perspective by assigning high allocation scores to ventilator-dependent patients. Many programs are now willing to maintain some ventilator-dependent patients on their active waiting list, anticipating that the high allocation score will expedite transplantation, but reserving the option of de-listing patients who develop intercurrent complications or progressive debility. An analysis of 586 ventilator-

dependent patients in the UNOS database documents inferior but not necessarily prohibitively poor short-term outcomes; 1-year and 2-year survival rates were 62% and 57%, respectively, compared with 79% and 70% for non-ventilated patients.¹⁵ Even more controversial is transplantation of patients on *extracorporeal membrane oxygenation* (ECMO) support, for whom 1-year and 2-year posttransplant survival rates were only 50% and 45%, respectively, in the UNOS database. More recent single-center reports document more promising outcomes,^{16,17} and increasing availability of ambulatory ECMO techniques may improve outcomes in the future.

TIMING OF REFERRAL AND LISTING

Listing for transplantation is considered at a time when the lung disease limits basic activities of daily living and is deemed to pose a high risk of death in the short term. Disease-specific guidelines for timely referral and listing of patients, based on available predictive indices, have been published (Table 106-1).⁹ The imprecise nature of these predictive indices can make decisions about transplant listing problematic for all but the most severely ill patients. The patient's perception of an unacceptably poor quality of life is an important additional factor to consider but should not serve as the sole justification for listing of a patient whose disease is not deemed to be at an advanced and potentially life-threatening stage.

ALLOCATION SYSTEM

Rules governing allocation of organs vary among countries but typically employ a time-based or need-based ranking of candidates on the waiting list, or some combination of the two systems. Examination of the systems that have been operative in the United States permits an appreciation of the advantages and limitations of both approaches. From 1990 to 2005, lung allocation in the United States prioritized candidates on the basis of the amount of time they had accrued on the waiting list, without regard to severity of illness. Based on a simple and objective parameter, this system was easily understood but was ultimately called into question because it failed to accommodate those patients with a more rapidly progressive course who often could not survive the prolonged waiting times.¹⁸ In response to the perceived inequities of the time-based system, and under mandate of the federal government, a new system was implemented in 2005. It allocates lungs on the basis of both medical urgency (risk of death without a transplant) and "net transplant benefit" (the extent to which transplantation will extend survival). It uses predictive models, incorporating more than a dozen variables, to generate predictions for a given patient of 1-year survival with and without transplantation.¹⁹ A raw *lung allocation score* (LAS) is then calculated on the basis of these survival predictions and normalized to a scale of 0 to 100 for ease of use. Because 1-year survival without transplantation is factored into net transplant benefit and medical urgency measures, it affects

Table 106-1 Disease-Specific Guidelines for Listing for Lung Transplantation**CHRONIC OBSTRUCTIVE PULMONARY DISEASE**

- BODE index of 7–10 **or** at least one of the following:
 - History of hospitalization for exacerbation associated with acute hypercapnia ($PCO_2 > 50$ mm Hg)
 - Pulmonary hypertension or cor pulmonale, or both, despite oxygen therapy
 - $FEV_1 < 20\%$ and either $DL_{CO} < 20\%$ or homogeneous distribution of emphysema

IDIOPATHIC PULMONARY FIBROSIS

- Histologic or radiographic evidence of UIP **and** any of the following:
 - $DL_{CO} < 39\%$ predicted
 - $\geq 10\%$ decrement in FVC during 6 months of follow-up
 - Decrease in pulse oximetry to $< 88\%$ during a 6MWT
 - Honeycombing on HRCT (fibrosis score > 2)

CYSTIC FIBROSIS

- $FEV_1 < 30\%$ of predicted or rapidly declining lung function if $FEV_1 > 30\%$ (females and patients < 18 yr have a poorer prognosis; consider earlier listing) **and/or** any of the following:
 - Increasing oxygen requirements
 - Hypercapnia
 - Pulmonary hypertension

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

- Persistent NYHA class III or IV on maximal medical therapy
- Low (350 m) or declining 6MWT
- Failing therapy with intravenous epoprostenol or equivalent
- Cardiac index < 2 L/min/m²
- Right atrial pressure > 15 mm Hg

SARCOIDOSIS

- NYHA functional class III or IV **and** any of the following:
 - Hypoxemia at rest
 - Pulmonary hypertension
 - Elevated right atrial pressure > 15 mm Hg

BODE, [b]ody mass index, airflow [o]bstruction, [d]yspnea, [e]xercise capacity; DL_{CO} , diffusing capacity for carbon dioxide; FEV_1 , forced expiratory volume in 1 second; FVC, forced vital capacity; HRCT, high-resolution computed tomography; 6MWT, 6-minute walk test; NYHA, New York Heart Association; PCO_2 , pressure of carbon dioxide; UIP, usual interstitial pneumonia.

Modified from Orens JB, Estenne M, Arcasoy S, et al: International guidelines for the selection of lung transplant candidates: 2006 update. *J Heart Lung Transplant* 25:745–755, 2006.

the LAS more than posttransplantation survival, which is used only in the net transplant benefit calculation. As designed, the system preferentially allocates lungs to sicker patients while attempting to avoid situations in which outcomes are so poor that there would be no meaningful survival benefit.

Since its implementation, the LAS system has had a profound and favorable effect on the dynamics of lung transplantation in the United States.²⁰ Because there is no longer an incentive to place patients on the active waiting list simply to accrue time (many of whom were ultimately deactivated rather than transplanted), the number of actively listed patients has fallen to approximately one half of the previous level. Median waiting time, which had ranged from 2 to 3 years under the time-based allocation system, has decreased to less than 6 months, and one quarter of patients are waiting less than 35 days. Importantly, there has been a significant reduction in the annual death rate

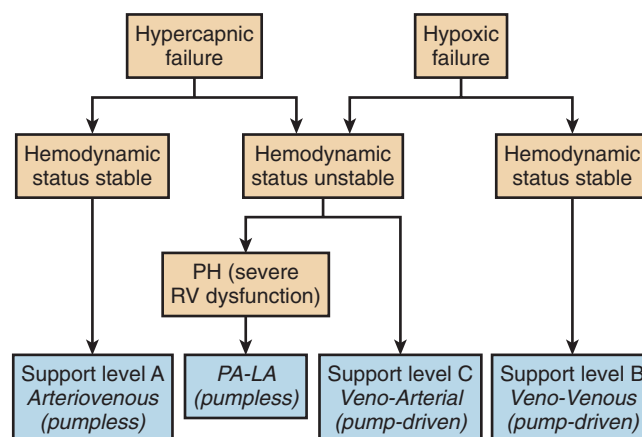

Figure 106-1 Selection of extracorporeal lung support device and configuration. The choice of support device is largely dependent on the type of respiratory failure (hypercarbic or hypoxic) and the hemodynamic status (stable or unstable). LA, left atrium; PA, pulmonary artery; PH, pulmonary hypertension; RV, right ventricle. (From Cypel M, Keshavjee S: Extracorporeal life support pre and post lung transplantation. ECMO Extracorporeal Cardiopulmonary Support in Critical Care (ELSO Red Book), ed 4. Ann Arbor, MI, 2011, Extracorporeal Life Support Organization.)

of patients on the waiting list, one of the stated objectives of the new system. Notably, preferential transplantation of sicker patients has not resulted in an increase in early mortality following transplantation. Further experience will be required to determine the impact of the new system on long-term outcomes following transplantation.

BRIDGING TO TRANSPLANTATION: ARTIFICIAL LUNG TECHNOLOGIES

As mentioned earlier, ECMO has been used to bridge critically ill patients to lung transplantation, though, historically, outcomes following transplantation have been suboptimal. Advances in artificial lung technology, including improved membranes, improved pumps, and even ambulatory support systems, make it increasingly possible to support selected patients successfully, permitting them to survive the wait for a suitable donor lung, and, importantly, to achieve a successful posttransplant outcome.²¹⁻²⁴

Patients with isolated hypercapnic failure can be bridged with pumpless devices such as the *interventional lung assist* (iLA) from Novalung, a low-resistance device with a meshwork of hollow fibers maximizing blood/gas diffusion; with this device, blood is propelled by arterial pressure. Patients requiring oxygenation support can be supported with veno-venous configured pump devices. Patients requiring circulatory support, as well as gas exchange support, can be managed with a conventional veno-arterial configuration. It is important to understand the underlying physiology of the patient and to select the device configuration that provides the necessary support (Fig. 106-1). An application unique to patients with pulmonary arterial hypertension is the application of the pumpless iLA device from pulmonary artery to left atrium

Table 106-2 Standard Lung Donor Criteria

- Age < 55 yr
- Clear chest radiograph
- PaO₂ > 300 mm Hg on FIO₂ 1.0, PEEP 5 cm H₂O
- Cigarette smoking history < 20 pack-years
- Absence of significant chest trauma
- No evidence of aspiration or sepsis
- No prior thoracic surgery on side of harvest
- Absence of organisms on sputum Gram stain
- Absence of purulent secretions and gastric contents at bronchoscopy
- Negative for HIV antibody, hepatitis B surface antigen, and hepatitis C antibody
- No active or recent history of malignancy (excluding localized squamous or basal cell skin cancer, localized cervical cancer, and primary brain tumors with low metastatic potential and in the absence of invasive procedures to the brain and skull)
- No history of significant chronic lung disease

FIO₂, fractional concentration of oxygen in inspired gas; HIV, human immunodeficiency virus; PaO₂, arterial oxygen pressure; PEEP, positive end-expiratory pressure.

to offload the right ventricle and provide an “oxygenating septostomy” physiology. This strategy has effectively abolished wait list mortality in the group of patients that traditionally has the highest mortality on the wait list.^{22,25}

DONOR SELECTION AND MANAGEMENT

In addition to meeting strict criteria for declaration of brain death, cadaveric lung donors are selected on the basis of established guidelines (Table 106-2).²⁶ Lungs are a particularly fragile organ in the brain-dead patient and are frequently compromised by volume overload, contusion, aspiration of gastric contents, or pneumonia, as well as by extensive prior smoking. As a result, the vast majority of donors fail to meet standard criteria for lung donation, leading to a historical recovery rate of only 15% from cadaveric organ donors deemed able to donate other organs. Although it is reasonable to be conservative with patient safety in mind, there is mounting evidence that these standard criteria may in fact be too stringent, leading to unnecessary wastage of suitable lungs. In one study, 29 pairs of lungs that had been rejected for transplantation were assessed for the magnitude of extravascular water content, intactness of alveolar fluid clearance capacity, and presence of pneumonia or emphysema.²⁷ Twelve pairs (41%) were found to have minimal or no abnormalities and thus to be “potentially suitable” for transplantation. Additional evidence comes from published reports documenting that outcomes with use of “extended criteria” donors are similar to those achieved with use of donors meeting standard criteria.²⁸⁻³² Use of modified donor management protocols to optimize lung function through judicious fluid management, therapeutic bronchoscopy, and lung recruitment maneuvers has also been shown to enhance lung retrieval rates.^{33,34} Additionally, a recent multicenter, randomized trial demonstrated that use of a low tidal volume, lung-protective ventilatory protocol (6 to 8 mL/kg; PEEP 8 to

10 cm H₂O) in brain-dead potential organ donors resulted in a doubling of lung harvest rates (54% vs. 27%) compared with a conventional ventilatory protocol (10 to 12 mL/kg; PEEP 3 to 5 cm H₂O).³⁵

Despite increases in the number of organs successfully retrieved, the demand for organs continues to outstrip supply, prompting a search for alternatives to the brain-dead donor pool. One emerging source is the non-heart-beating or *donation after cardiac death* (DCD) donor who has experienced either an out-of-hospital (i.e., uncontrolled) arrest or a planned withdrawal of life support in the operating room. Currently only 1% of lung transplants performed in the United States utilize DCD donors⁵; in contrast, DCD donors account for 12% of lung transplants in Australia.³⁶ Data suggest that short- and medium-term outcomes are as good as or better than those associated with use of traditional brain-dead donors.^{36,37}

Once a donor has been identified, matching with potential recipients is based on size and ABO blood group compatibility. Prospective *human leukocyte antigen* (HLA) matching is not performed. However, potential candidates identified through standard pretransplant screening as having preformed circulating antibodies to foreign HLA antigens require either prospective donor-recipient lymphocytotoxic cross-matching or avoidance of donors with specific incompatible antigens.³⁸

LUNG PRESERVATION

The standard of lung preservation is hypothermic flush preservation. The most commonly used solution is Perfadex (Vitrolife, Sweden). Cold flush preservation at 4° C decreases the metabolic rate to 5% of normal and hence slows down the dying process of the lung. Although this approach has been useful for clinical lung transplantation, cold static preservation has significant limitations: (1) a decision regarding utilization must be made quickly with limited information in the donor hospital; (2) once the organ is flushed, there is no second chance to reevaluate the organ before removal of the cross clamp at reperfusion; and (3) the focus is on slowing down the dying process and it does not address or take advantage of opportunities to diagnose, treat, repair, or regenerate the donor lung.

Ex vivo lung perfusion has been developed to address these limitations. It is now possible to perfuse lungs ex vivo at normothermia for extended periods, thus creating a platform for more detailed assessment of lung function, more accurate diagnosis, and targeted treatment of donor lung injuries to improve the function of the lung after transplantation.³⁹⁻⁴¹ This creates the opportunity to engineer donor organs with gene therapy, cell therapy, and other advanced treatments to create “super-organs” that hopefully will one day afford the recipient long-term allograft function.^{42,43}

Ex vivo lung perfusion has been shown to increase donor lung utilization of lungs that previously could not be used.^{40,44} Short-term outcomes using lungs conditioned in this fashion have been highly favorable.^{40,41} Ex vivo lung perfusion is now standard practice in the Toronto Lung Transplant Program⁴¹ and is being increasingly applied worldwide.⁴⁵ The U.S. Food and Drug Administration

recently approved the XVIVO Perfusion System for use in the United States.

AVAILABLE SURGICAL TECHNIQUES

Four surgical techniques have been developed: *heart-lung transplantation* (HLT), *single-lung transplantation* (SLT), *bilateral-lung transplantation* (BLT), and living donor bilobar transplantation. The choice of procedure is dictated by such factors as the underlying disease, age of the patient, survival and functional advantages, donor organ availability, and center-specific preferences. Currently, SLT and BLT account for more than 97% of all procedures performed.¹

HEART-LUNG TRANSPLANTATION

HLT was the first procedure to be performed successfully, but it has largely been supplanted by techniques to replace the lungs alone. Currently, fewer than 100 procedures are performed worldwide annually.¹ Indications are largely restricted to Eisenmenger syndrome with surgically uncorrectable cardiac lesions and to advanced lung disease with concurrent severe left ventricular dysfunction or extensive coronary artery disease. In the past, the presence of profound right ventricular dysfunction in the setting of severe pulmonary hypertension was deemed to be an indication for heart-lung transplantation. However, subsequent experience with isolated lung transplantation has demonstrated the remarkable ability of the right ventricle to recover once pulmonary artery pressures have normalized.

SINGLE-LUNG TRANSPLANTATION

SLT was, until recently, the most commonly performed procedure. Traditionally, a standard posterolateral thoracotomy was utilized, but some surgeons now employ a less invasive anterior axillary muscle-sparing approach in selected cases. Three anastomoses are executed—mainstem bronchus, pulmonary artery, and left atrium (incorporating the two pulmonary veins). Compared with BLT, SLT permits more efficient use of the limited donor supply and is better tolerated by less robust patients, but it provides less functional reserve in the setting of allograft dysfunction. It is an acceptable option for patients with pulmonary fibrosis and COPD. SLT has also been performed successfully in carefully selected patients with severe pulmonary hypertension. In this setting, however, there is an increased risk of perioperative allograft edema because the freshly transplanted lung must bear the burden of nearly the entire cardiac output. This concern has prompted the vast majority of centers to abandon this approach in favor of the bilateral procedure. Because of infectious concerns, SLT is contraindicated in patients with suppurative lung disorders such as CF.

BILATERAL-LUNG TRANSPLANTATION

BLT involves the performance of two single-lung transplant procedures in succession during a single operative session.

Surgical approaches include transverse thoracosternotomy (“clamshell”) incision, bilateral anterolateral thoracotomies (sparing the sternum), and median sternotomy. In the absence of severe pulmonary hypertension, cardiopulmonary bypass can often be avoided by sustaining the patient on the contralateral lung during implantation of each allograft. The principal indications for this procedure are CF, other forms of bronchiectasis, and severe primary and secondary forms of pulmonary hypertension. In addition, many programs now advocate its use for patients with COPD, arguing that it offers functional and survival advantages over SLT.⁴⁶⁻⁴⁹ Although it is also being employed with increasing frequency in treatment of fibrotic lung disorders, the justification for this is less clear.^{50,51} As a result of these trends, BLT now accounts for three quarters of all procedures performed worldwide.¹

LIVING DONOR BILOBAR TRANSPLANTATION

Living donor bilateral-lobar transplantation was developed chiefly to serve the needs of candidates with far-advanced or deteriorating status that would not allow them to tolerate a protracted wait for a cadaveric donor. The procedure involves transplantation of lower lobes from each of two living, blood group-compatible donors. In order to ensure that the lobes will adequately fill the hemithoraces, it is preferable to employ donors who are taller than the recipient. Patients with CF are particularly well suited as a target population because, even as adults, they tend to be of small stature. Intermediate-term functional outcomes and survival among recipients are similar to those achieved with cadaveric transplantation.^{52,53} Concerns about excessive risk to the donor have thus far proved to be unfounded. In the two largest series published to date involving a combined total of 315 donors, there were no deaths or episodes of postoperative respiratory failure, and only 9 donors (2.9%) experienced complications of sufficient magnitude to warrant surgical reexploration.^{54,55} Donation of a lobe results in an average decrement in vital capacity of 17%, a degree of loss that should be of little functional significance in an otherwise normal individual.⁵⁶ Despite the apparent low risk posed to the donor, living donor transplantation has not gained widespread acceptance. Its use has been further undermined by the LAS allocation system, which expedites transplantation of more severely ill candidates; only nine living-donor transplantation procedures have been performed in the United States since implementation of the LAS system.⁵

ROUTINE POSTTRANSPLANTATION MANAGEMENT AND OUTCOMES

Care of the lung transplant recipient requires close surveillance to ensure that the allograft is functioning properly, that immunosuppressive medications are properly administered and tolerated, and that complications are detected early and treated expeditiously. Most centers require patients to return frequently for office visits, blood tests, and chest

radiographs during the initial 2 to 3 months following transplantation and to participate in an intensive pulmonary rehabilitation program during this time. Analogous to home glucose monitoring of the diabetic patient, lung transplant recipients chart their pulmonary function on a daily basis with a handheld microspirometer and are instructed to contact the transplant center if a sustained fall of greater than 10% in the *forced expiratory volume in 1 second* (FEV₁) or forced vital capacity is documented.

Many transplant programs employ frequent surveillance bronchoscopies and transbronchial lung biopsies within the first posttransplant year as a means of monitoring the allograft. Such an approach has been demonstrated to detect low-grade rejection and subclinical *cytomegalovirus* (CMV) pneumonitis in up to 30% of asymptomatic, clinically stable patients.⁵⁷ However, it has yet to be determined whether treatment of clinically silent disease has a beneficial impact on long-term graft function.

Immunosuppressive therapy is initiated immediately at the time of transplantation and is maintained lifelong. No consensus currently exists on the role of induction therapy with lymphocyte/thymocyte-depleting globulin preparations or *interleukin-2* (IL-2) receptor antagonists (basiliximab and daclizumab), and only half of all centers currently employ this strategy.¹ The lack of consensus reflects insufficient and conflicting data on the ability of these agents to reduce the incidence of acute rejection and *bronchiolitis obliterans syndrome* (BOS) in the lung transplant population. Maintenance therapy consists of a calcineurin inhibitor (cyclosporine or tacrolimus), purine synthesis inhibitor (azathioprine or mycophenolate), and prednisone. Sirolimus (also known as *rapamycin*), an inhibitor of IL-2-stimulated T-cell proliferation, is the newest immunosuppressive agent to be introduced into clinical practice. Use of this agent in place of a purine synthesis inhibitor does not reduce the incidence of acute rejection or BOS and is associated with a number of bothersome side effects that commonly lead to discontinuation of the drug.⁵⁸ Lacking inherent nephrotoxicity, sirolimus has been successfully substituted for calcineurin inhibitors in patients with renal insufficiency, leading to recovery of renal function without undue risk of rejection.^{59,60} Sirolimus impairs wound healing and has been associated with life-threatening bronchial anastomotic dehiscence when used immediately following transplantation.⁶¹ As a result, the drug should never be initiated until complete healing of the bronchial anastomosis has been documented.

Individuals providing care to transplant recipients must be familiar with the administration, side effects, and drug interactions of these immunosuppressive agents (Table 106-3). Although serving as the cornerstone of therapy, the use of calcineurin inhibitors is particularly challenging. When administered orally, the bioavailability of these agents is poor and unpredictable, necessitating frequent monitoring of blood levels to ensure appropriate dosing. These drugs are metabolized via the hepatic cytochrome P-450 system, and blood levels are influenced by the concurrent administration of other drugs that affect this enzymatic pathway. Adverse effects of these agents, as well as of the other drugs commonly utilized, are legion and contribute significantly to the morbidity associated with transplantation.

Management of medical comorbidities is an essential component of the care of the lung transplant recipient. Common medical issues that emerge in this population include osteoporosis, hypertension, renal insufficiency, coronary artery disease, diabetes mellitus, and hyperlipidemia.⁶² Treatment of these conditions is similar to that of the general population.

SURVIVAL

Current 1-, 5-, and 10-year survival rates following lung transplantation are 82%, 55%, and 33%, respectively. Survival rates have steadily improved over time, as indicated by an increase in median survival from 3.9 years in 1990–1997 to 6.1 years in 2005–2012.¹ Disease-specific differences in survival are apparent but may be confounded by differences in severity of illness, comorbidities, and average age among these populations. In descending order, median survival is 8.3 years for CF, 6.4 years for α_1 -antitrypsin deficiency, 5.7 years for sarcoidosis, 5.5 years for COPD and IPA, and 4.7 years for IPE.¹

Mortality is highest during the first year, with primary graft dysfunction and infection representing the most common causes of death. Factors portending an increased risk of early death include ventilator dependence of the recipient before transplantation, a pretransplant diagnosis of pulmonary arterial hypertension, elevated bilirubin, and advanced recipient age.¹ Beyond the first year, attrition slows to an annual rate of approximately 5% to 8%. Most late deaths are attributable to the development of BOS, the lethal effects of which are due to both progressive respiratory failure and an increased susceptibility to infection.

Whether lung transplantation truly extends survival compared with the natural history of the underlying disease remains a matter of some debate. In the absence of randomized trials, this question has been approached by comparing observed posttransplant survival to survival of wait-list patients or by simulating survival with and without transplantation by statistical modeling; both of these approaches suffer from significant methodologic shortcomings. In the case of IPE, a disease with an extremely poor short-term prognosis, studies have suggested that lung transplantation does confer a survival advantage.^{18,63} This has been more difficult to demonstrate for COPD, which typically follows a protracted course even in the advanced stages, and available studies comparing wait list and posttransplant survival have yielded conflicting results.^{18,64,65} A more complex analysis of this issue, employing prognostic models of survival with and without transplantation, found that approximately 45% of COPD patients would gain a survival benefit of at least 1 year by undergoing BLT; only 22% would derive such a benefit if SLT were employed.⁴⁹ Survival benefit was heavily influenced by pretransplant FEV₁, as well as a number of other functional and physiologic parameters. As an example, nearly 80% of patients with an FEV₁ less than 16% but only 11% of those with an FEV₁ greater than 25% were predicted to gain at least a year of life with BLT. Adults with CF also appear to derive a survival advantage from lung transplantation, though one study found that this was limited to those patients with a predicted 5-year survival without transplantation of less than 50% and without

Table 106-3 Commonly Used Immunosuppressive Medications

Medication (Class)	Dosing*	Adverse Effects	Drug Interactions
Cyclosporine and tacrolimus (calcineurin inhibitors)	Cyclosporine: dosed to achieve a whole blood trough level of 250–350 ng/mL (first year), then 200–300 ng/mL [†] Tacrolimus: dosed to achieve a whole blood trough level of 10–12 ng/mL (first year), then 6–8 ng/mL	Nephrotoxicity Hypertension Neurotoxicity (tremor, seizures, white matter disease, headache) Hyperkalemia Hypomagnesemia Hyperuricemia/gout Hemolytic-uremic syndrome Gastroparesis Hyperglycemia Hirsutism (cyclosporine) Gingival hyperplasia (cyclosporine)	INCREASED BLOOD LEVELS Macrolide antibiotics (except azithromycin) Azole antifungals Diltiazem, verapamil Grapefruit juice DECREASED BLOOD LEVELS Phenobarbital Phenytoin Rifampin
Sirolimus (mTOR inhibitor)	Dosed to achieve a whole blood trough level of 6–12 ng/mL	Thrombocytopenia Anemia Hyperlipidemia Peripheral edema Rash Impaired wound healing Interstitial pneumonitis	Same as calcineurin inhibitors
Azathioprine (purine synthesis inhibitor)	2 mg/kg/day	Leukopenia Macrocytic anemia Thrombocytopenia Hepatotoxicity Pancreatitis Hypersensitivity reaction (fever, hypotension, rash)	Synergistic bone marrow suppression when administered with allopurinol
Mycophenolate mofetil (purine synthesis inhibitor)	1000–1500 mg bid	Diarrhea Leukopenia Anemia	Concurrent use of cyclosporine may decrease serum concentrations of mycophenolate by limiting biliary secretion/enterohepatic recycling
Prednisone (corticosteroid)	0.5 mg/kg/day for 6–12 wk, then tapered to 0.15 mg/kg/day	Hyperglycemia Hypertension Hyperlipidemia Weight gain Osteoporosis Avascular necrosis Myopathy Mood changes Insomnia Cataracts	No significant interactions
Polyclonal antilymphocyte or antithymocyte globulin	Dose depends on specific preparation used	Leukopenia Thrombocytopenia Anaphylaxis Serum sickness “Cytokine release syndrome”—fever, hypotension	No significant interactions
Basiliximab (monoclonal IL-2 receptor antagonist)	20 mg IV on days 1 and 4	Hypersensitivity reactions (rare)	No significant interactions

*Dosing is based on the protocol used at the Hospital of the University of Pennsylvania; dosing may vary among transplant centers.

[†]Measured by high-performance liquid chromatography assay.

IL-2, interleukin-2.

B. cepacia and CF-arthritis.^{66,67} In contrast, modeling studies have suggested that CF patients younger than 18 years old rarely achieve a survival benefit.^{66,68} This contention has been challenged by several authors, who point out potential methodologic shortcomings of these studies.^{69,70}

PULMONARY FUNCTION

The peak effect of lung transplantation on pulmonary function parameters is usually not realized until 3 to 6 months following the procedure, at which time the adverse impact of such factors as postoperative pain, weakness, altered

chest wall mechanics, and ischemia-reperfusion lung injury has dissipated. Complete normalization of pulmonary function is the anticipated result of BLT. Following SLT for COPD, the FEV₁ increases several fold to a level of approximately 50% to 60% of the predicted normal value (Video 106-1). Similarly, SLT for pulmonary fibrosis results in marked but incomplete improvement in lung volumes, with persistence of a restrictive pattern.

Transplantation also leads to correction of gas exchange abnormalities. Oxygenation improves rapidly, permitting the majority of patients to be weaned off of supplemental oxygen within the first week. Hypercapnia may take longer

to resolve, due to lingering abnormalities in the ventilatory response to carbon dioxide.⁷¹

EXERCISE CAPACITY

Exercise tolerance improves sufficiently to permit the majority of transplant recipients to achieve functional independence and resume an active lifestyle. Although free of limitations with usual activity, transplant recipients with normal allograft function demonstrate a characteristic reduction in peak exercise performance as assessed by cardiopulmonary exercise testing. Specifically, patients typically achieve a maximum oxygen consumption at peak exercise of only 40% to 60% of predicted.⁷² Suboptimal exercise performance persists in subjects tested as late as 1 to 2 years following transplantation. Despite the greater magnitude of improvement in pulmonary function experienced by bilateral transplant recipients, there is no significant difference in peak exercise performance between this group and those who receive only one lung.⁷³

Characteristically, breathing reserve, oxygen saturation, and heart rate reserve remain normal during exercise while anaerobic threshold is reduced, a pattern most consistent with skeletal muscle dysfunction. Factors possibly contributing to this include chronic deconditioning, steroid myopathy, and calcineurin inhibitor-induced impairment in muscle mitochondrial respiration.^{72,74}

HEMODYNAMICS

When performed in patients with pulmonary hypertension, both SLT and BLT lead to immediate and sustained normalization of pulmonary arterial pressure and enhanced cardiac output.⁷⁵ In response to a decrease in afterload, right ventricular geometry and performance gradually normalize in the majority of patients.^{76,77} A threshold of right ventricular dysfunction below which recovery will not happen has yet to be defined.

QUALITY OF LIFE

After successful lung transplantation, quality of life measures improve markedly across most domains, achieving levels approximating that of the general population.⁷⁸⁻⁸² Nonetheless, several important limitations have been observed. Although improved from pretransplant status, impairments in psychological functioning—including increased levels of depression and anxiety, and poor perception of body image—persist.^{78,79} In addition, troubling side effects from immunosuppressive medications adversely affect quality of life.^{79,82} Finally, the development of BOS is associated with a significant deterioration in quality of life measures.⁸¹

Despite improvements in performance status and quality of life, fewer than half of lung transplant recipients return to the workforce.^{83,84} Factors cited by recipients as barriers to employment include employer bias against hiring an individual with a chronic medical condition, the potential loss of disability income or medical benefits, side effects of medications, concerns about risk of infection in the workplace, and prioritization of recreational activities over work as a posttransplantation goal.

COMPLICATIONS

PRIMARY GRAFT DYSFUNCTION

Primary graft dysfunction (PGD) is a term applied to the development within 72 hours of transplantation of radiographic opacities in the allograft(s) associated with impaired oxygenation, in the absence of identifiable insults such as volume overload, pneumonia, rejection, atelectasis, or pulmonary venous outflow obstruction.⁸⁵ PGD is presumed to be a consequence of ischemia-reperfusion injury, but inflammatory events associated with donor brain death, surgical trauma, and lymphatic disruption may be contributing factors. Supporting the concept of PGD as a form of acute, nonimmunologic lung injury, histologic examination of lung tissue from affected patients reveals a prevailing pattern of diffuse alveolar damage.⁸⁵ A widely used grading system classifies the severity of PGD based on the arterial oxygen pressure-to-fractional concentration of oxygen in inspired gas (arterial PO_2/FiO_2) ratio (Table 106-4).⁸⁶ In most cases, the process is mild and transient, but in approximately 10% to 20% of cases, injury is sufficiently severe to cause life-threatening hypoxemia (PGD grade 3) and a clinical course analogous to the acute respiratory distress syndrome.

A recent prospective, multicenter cohort study identified a number of risk factors for development of severe PGD.⁸⁷ Many of these were procedure-related factors: use of an elevated FiO_2 during reperfusion, use of cardiopulmonary bypass, SLT, and administration of large volume blood product transfusions. Recipient risk factors were a diagnosis of sarcoidosis, presence of pulmonary hypertension, and overweight or obese body habitus. The only donor-related risk factor identified was a history of smoking. Notably, graft ischemic time was not identified as a risk factor in this study. In another study, an elevated level of IL-8 in bronchoalveolar lavage (BAL) fluid recovered from the donor was associated with the development of severe PGD, supporting the notion that inflammatory events preceding organ harvest may play a role.⁸⁸

Treatment of severe PGD is supportive, relying on conventional mechanical ventilation utilizing low tidal volume strategies, as well as on such adjunct measures as independent lung ventilation and extracorporeal life support for selected patients who otherwise cannot be stabilized.^{89,90}

Table 106-4 Grading System for Primary Graft Dysfunction

Grade	PaO_2/FiO_2	Radiographic Evidence of Pulmonary Edema
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

PaO_2/FiO_2 , ratio of arterial oxygen pressure to fractional concentration of oxygen in inspired gas.

From Christie JD, Carby M, Bag R, et al: Report of the ISHLT Working Group on Primary Lung Graft Dysfunction Part II: Definition. A consensus statement of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant* 24:1454–1459, 2005.

Figure 106-2 Bronchial anastomotic dehiscence. **A**, Bronchoscopic view immediately distal to the main carina demonstrates partial dehiscence of the right bronchial anastomosis at the 1 o'clock position. **B**, After several weeks of expectant management, a repeat bronchoscopy demonstrates near-complete healing of the dehiscence.

The use of nitric oxide in patients with established graft injury has been associated with sustained reduction in pulmonary artery pressures and improvement in oxygenation.⁹¹ However, the prophylactic administration of nitric oxide to all recipients at the time of reperfusion does not reduce the incidence of severe PGD.⁹² Results of emergency retransplantation in this setting have been poor.^{93,94}

With an associated perioperative mortality rate of 20% to 40%, severe PGD is a leading cause of early deaths among transplant recipients.^{87,95,96} The risk of death remains excessive even beyond the first year, suggesting that PGD has lingering adverse consequences well after resolution of the acute event. Recovery among survivors is often protracted and incomplete, though attainment of normal lung function and exercise tolerance is possible.⁹⁷ There appears to be an increased risk of BOS following development of PGD, but data are conflicting on whether the increased risk spans all grades of PGD or is seen exclusively following the most severe grade.^{98,99}

AIRWAY COMPLICATIONS

During implantation of the allograft, no attempt is routinely made to reestablish the bronchial arterial circulation. As a consequence, the donor bronchus is precariously dependent on retrograde blood flow through low-pressure pulmonary venous to bronchial vascular collaterals, placing the airway at risk for ischemic injury. Rarely, this may result in bronchial anastomotic dehiscence, which, when extensive, can lead to mediastinitis, pneumothorax, hemorrhage, and death. Treatment of this life-threatening complication previously required risky and often unsuccessful surgical intervention to buttress the anastomosis. More recently, success has been reported with temporary placement of a bare metal airway stent across the dehiscence in order to provide a scaffolding on which granulation tissue can form.¹⁰⁰ For lesser degrees of dehiscence, conservative management with reduction in corticosteroid dosing and chest

Figure 106-3 Bronchial anastomotic stricture. Bronchoscopic view of a left main-stem bronchial anastomosis demonstrates marked narrowing of the lumen due to formation of a fibrous web. The true outer margin of the bronchus is outlined by the suture material.

tube evacuation of associated pneumothorax will often lead to successful healing (Fig. 106-2).

Ischemic injury to the airway more commonly manifests as necrosis of the anastomotic cartilage and as patchy areas of bronchial mucosal ulceration and pseudomembranes. These devitalized areas in turn place the patient at increased risk for fungal superinfection of the airway (see later).

The most common airway complication currently encountered is bronchial anastomotic stenosis, with a reported frequency of 10% to 15% in contemporary series.^{101,102} Narrowing can be due to excessive granulation tissue, fibrotic stricture (Fig. 106-3), or bronchomalacia

(the latter two mechanisms likely a sequela of prior ischemic injury). Occasionally, fibrotic strictures can extend beyond the anastomosis, leading to narrowing of the bronchus intermedius (eFig. 106-1) or lobar bronchi. Anastomotic narrowing typically develops within several weeks to months following transplantation. Clues to its presence include focal wheezing on the involved side, recurrent bouts of pneumonia or purulent bronchitis, and suboptimal pulmonary function studies demonstrating airflow obstruction and truncation of the flow-volume loop. Bronchoscopy both confirms the diagnosis and permits therapeutic interventions including balloon dilation, laser debridement, endobronchial brachytherapy, and stent placement.¹⁰³ Although these measures are often successful in the short term, recurrent stenosis is common, necessitating repeated interventions and leading to compromised functional outcomes and excess mortality.¹⁰⁴

PHRENIC NERVE INJURY

Phrenic nerve injury following lung transplantation can result from intraoperative traction, use of an iced slurry to cool the allograft in the chest cavity before reperfusion, or transection of the nerve in the setting of extensive fibrous adhesions and difficult hilar dissection. Depending in part on whether screening is restricted to clinically suspected cases or more broadly to all recipients, the reported incidence of phrenic nerve injury ranges from 3% to 30%.¹⁰⁵⁻¹⁰⁸ Important albeit nonspecific clues to the presence of phrenic nerve injury include difficulty in weaning from mechanical ventilation, persistent hypercapnia, orthopnea, and radiographic evidence of persistent elevation of the diaphragm and associated basilar atelectasis. Phrenic nerve injury has been associated with increases in ventilator days, tracheostomy rates, and intensive care unit length of stay.¹⁰⁶ Achievement of a normal functional outcome is ultimately possible for those with reversible injury, but recovery in some cases may be protracted or incomplete. For severely impaired patients, nocturnal noninvasive ventilatory support and diaphragmatic plication have been successfully employed.^{109,110}

NATIVE LUNG HYPERINFLATION

Acute hyperinflation of the native lung leading to respiratory and hemodynamic compromise in the immediate postoperative period has been reported in 15% to 30% of emphysema patients undergoing SLT.^{111,112} Although risk factors remain poorly defined, the combination of positive-pressure ventilation and significant allograft edema serves to magnify the compliance differential between the two lungs and may predispose to this complication. Acute hyperinflation can be rapidly addressed by initiation of independent lung ventilation, ventilating the native lung with a low respiratory rate and a long expiratory time to facilitate complete emptying. Beyond the perioperative period, some SLT recipients with underlying emphysema demonstrate exaggerated or progressive native lung hyperinflation that more insidiously compromises the function of the allograft. In this setting, surgical volume reduction of the native lung can result in significant functional improvement.¹¹³

INFECTION

Infection rates among lung transplant recipients are several fold higher than among recipients of other solid organs. The greater risk is likely related to the unique exposure of the lung allograft to microorganisms via inhalation and aspiration and to the higher level of immunosuppression maintained in these patients. A comprehensive discussion of infectious complications is beyond the scope of this chapter; only the most common pathogens are discussed.

Bacteria

Bacterial infections of the lower respiratory tract account for the majority of infectious complications and have a bimodal temporal distribution.^{114,115} Bacterial pneumonia is most frequently encountered within the first month post-transplantation. In addition to the immunosuppressed status of the recipient, factors that predispose to early bacterial pneumonia include the need for prolonged mechanical ventilatory support, blunted cough due to postoperative pain and weakness, disruption of lymphatics, and ischemic injury to the bronchial mucosa with resultant impairment in mucociliary clearance. Although passive transfer of occult infection with the transplanted organ is an additional concern, the presence of organisms on Gram stain of donor bronchial washings is not predictive of subsequent pneumonia in the recipient.¹¹⁶ Bacterial infections, in the form of purulent bronchitis, bronchiectasis, and pneumonia, reemerge as a late complication among patients who develop BOS. Gram-negative pathogens, in particular *P. aeruginosa* (see eFig. 91-1), are most frequently isolated in association with both early and late infectious events.^{114,115}

Cytomegalovirus

CMV is the most common viral pathogen encountered following lung transplantation, though in the era of effective prophylaxis, its incidence and impact have diminished considerably.¹¹⁵ Infection can develop by transfer of virus with the allograft or transfused blood products or by reactivation of latent virus remotely acquired by the recipient. Seronegative recipients who acquire organs from seropositive donors are at greatest risk for developing infection, and these primary infections tend to be the most severe. Although donor-positive/recipient-negative mismatching has been identified as a risk factor for increased mortality in the International Society for Heart and Lung Transplantation Registry,¹ this may no longer be the case with the current widespread use of effective prophylactic regimens.¹¹⁷

In the absence of prophylaxis, CMV infection typically emerges 1 to 3 months following transplantation; antiviral prophylaxis shifts the onset to later in the course, often in the initial months after the antiviral agent is discontinued. Infection is often subclinical, evidenced only by silent viremia or shedding of virus in the respiratory tract. Clinical disease may present as a mononucleosis-like syndrome of fever, malaise, and leukopenia ("CMV syndrome") or as organ-specific invasion of the lung, gastrointestinal tract, central nervous system, or retina. Detection of virus in peripheral blood by either the pp65 antigenemia assay or *polymerase chain reaction* (PCR) techniques establishes a diagnosis of CMV infection but does not necessarily reflect

events at the tissue level. A diagnosis of CMV pneumonia, the most common manifestation of invasive disease in the lung transplant recipient (see eFigs. 91-2 and 91-3), is unequivocally established only by demonstration of characteristic viral cytopathic changes on lung biopsy or on cytologic specimens obtained by BAL, but the sensitivity of these findings is relatively low. Caution must be exercised in interpretation of a positive viral culture or PCR of BAL specimens because virus can be shed into the respiratory tract in the absence of tissue invasion.

Standard treatment of CMV syndrome and tissue-invasive disease consists of a 2- to 3-week course of intravenous ganciclovir at a dose of 5 mg/kg twice daily, adjusted for renal insufficiency. Monitoring of peripheral blood viral load should be performed weekly to confirm response to therapy. Treatment should be continued until at least 1 week after an undetectable viral load is documented.¹¹⁸ Some experts advocate the addition of CMV hyperimmune globulin in treatment of severe disease, but evidence supporting this practice is scant. Although treatment is effective, relapse rates of up to 60% in primary infection and 20% in seropositive recipients have been reported.¹¹⁹ Initiation of oral valganciclovir as secondary prophylaxis after completion of definitive treatment is a common practice, but its impact on relapse rates is uncertain.

In an attempt to minimize the adverse impact of CMV infection on the posttransplantation course, emphasis has shifted to preventive strategies. Numerous prospective, randomized trials have documented the efficacy of antiviral prophylaxis in delaying the onset and reducing the incidence and severity of CMV infection.¹²⁰ Oral valganciclovir has largely replaced intravenous ganciclovir as the prophylactic agent of choice, due to its excellent bioavailability, ease of administration, and demonstrated efficacy.¹²¹ Universal prophylaxis of all donor-seropositive/recipient-seronegative patients is recommended because the risk of CMV disease is high.¹¹⁸ Because the risk of disease is significantly lower in seropositive recipients (independent of donor status), it has been argued that universal prophylaxis of this group leads to overtreatment, increasing costs and unduly exposing patients to the risk of drug toxicity. In this population, preemptive strategies targeting antiviral therapy exclusively to patients demonstrating a rising viral load in peripheral blood have been advocated, but many programs still adhere to a universal prophylaxis strategy.¹²² Consensus guidelines recommend a minimum of 6 months of prophylaxis for donor-positive/recipient-negative patients and 3 to 6 months for recipient-positive patients.¹²³ However, a recent randomized, controlled trial of at-risk lung transplant recipients (either donor or recipient seropositive) demonstrated a marked reduction in the incidence of CMV disease with use of a 12-month course of valganciclovir prophylaxis compared with a 3-month course (4% vs. 32%).¹²⁴ Additional studies are required to determine whether 12 months is necessary or excessive and whether all at-risk subgroups require the same regimen.

Emergence of ganciclovir-resistant strains of CMV has been reported in 5% to 15% of lung transplant recipients with CMV infection.^{125,126} Risk factors that have been identified include donor-positive/recipient-negative CMV status, use of potent immunosuppressive agents such as antilymphocyte antibodies and daclizumab, increased number of

CMV episodes, and prolonged exposure to ganciclovir.^{127,128} Foscarnet, administered alone or in combination with ganciclovir, is the agent of choice for treatment of ganciclovir-resistant disease.¹²⁶ The drug is potentially nephrotoxic, and careful monitoring of renal function is essential. Although treatment is often successful, the presence of ganciclovir-resistant disease is associated with decreased survival in lung transplant recipients.^{128,129}

Aspergillus

Aspergillus species are the most frequently encountered fungal pathogens among lung transplant recipients. As a ubiquitous organism acquired by inhalation, *Aspergillus* colonizes the airways of approximately one quarter of transplant recipients.¹³⁰ Airway colonization itself does not appear to pose a major risk of subsequent progression to invasive disease.¹³⁰ Whether this is due to the inherently benign nature of colonization or to the common practice of initiating fungal prophylaxis when colonization is detected is unclear.

Aspergillus infects the bronchial tree in approximately 5% of lung transplant recipients.¹³⁰ In most cases, infection is localized to the bronchial anastomosis, where devitalized cartilage and foreign suture material create a nurturing environment. Less commonly, infection may present as a more diffuse ulcerative bronchitis with formation of pseudomembranes, typically following in the wake of a severe ischemic injury to the bronchial mucosa. Clustered within the first 6 months posttransplantation, these airway infections are usually asymptomatic and detected only by surveillance bronchoscopy. Although usually responsive to oral azoles or to inhaled or intravenous amphotericin, airway infections have rarely progressed to invasive pneumonia or have resulted in fatal erosion into the adjacent pulmonary artery.^{130,131} An increased risk of subsequent bronchial stenosis or bronchomalacia has also been reported, but it is unclear whether this is a consequence of the infection or of an underlying ischemic injury to the bronchus that predisposed to infection.^{132,133}

Invasive aspergillosis, a far more serious form of infection, develops in 5% of lung transplant recipients, most commonly within the first year.¹³⁰ It nearly always involves the lung but may disseminate to distant sites, particularly the brain, in a minority of patients. Symptoms are nonspecific and include fever, cough, pleuritic chest pain, and hemoptysis. Radiographically, pulmonary aspergillosis may appear as single (see eFigs. 91-7 and 91-8B) or multiple nodular (see eFig. 91-8A) or cavitary opacities or as alveolar consolidation (Fig. 106-4). The "halo sign"—a rim of ground-glass attenuation surrounding a central nodular opacity—is a suggestive but uncommon finding on chest computed tomography (CT) scans.

Diagnosing invasive pulmonary aspergillosis can be challenging. As discussed previously, many lung transplant recipients are colonized with *Aspergillus*, making it difficult to interpret the significance of positive fungal stains and cultures derived from BAL specimens. Conversely, the sensitivity of bronchoscopic studies has been reported in the range of only 45% to 62% in solid organ transplant recipients with invasive disease.¹³⁴ Measurement of galactomannan levels in serum or BAL fluid has been touted as a useful test for establishing a diagnosis of invasive disease in certain

Figure 106-4 Invasive aspergillosis. Bilateral lung transplant recipient with a large right upper lobe cavity containing an air-fluid level. Transthoracic needle biopsy demonstrated fungal elements morphologically consistent with *Aspergillus* species. The patient failed to respond to antifungal therapy and required surgical resection for definitive cure.

patient populations; preliminary experience in lung transplant recipients suggests an unacceptably low sensitivity for both serum and BAL, though specificity appears to be high.^{135,136} In the context of compatible clinical and radiographic features and/or demonstration of *Aspergillus* in respiratory secretions by culture or cytology, the clinician must exercise judgment in deciding whether to initiate an empirical trial of antifungal therapy or pursue more definitive proof by means of transthoracic needle biopsy or surgical lung biopsy.

Amphotericin B was traditionally the mainstay of therapy for invasive aspergillosis. More recently, however, the triazole voriconazole has been shown to have superior efficacy and less toxicity than amphotericin B and has emerged as the treatment of choice.¹³⁷ Voriconazole is a potent inhibitor of the cytochrome P-450 hepatic enzyme system and can lead to dangerously high blood levels of concurrently administered calcineurin inhibitors and sirolimus if appropriate adjustments in the dosing of these agents are not made. The echinocandins (e.g., caspofungin) represent a third class of agents that have been successfully employed in the treatment of invasive aspergillosis.¹³⁸ Despite the availability of antifungal therapy, mortality rates in the range of 60% to 80% have been reported.^{130,139} The therapeutic role of surgical resection remains uncertain, but surgery has been advocated in cases of localized infection refractory to medical therapy.^{140,141}

REJECTION AND CHRONIC ALLOGRAFT DYSFUNCTION

Despite the use of potent immunosuppressive agents, allograft rejection and chronic allograft dysfunction remain pervasive problems that constrain long-term graft and patient survival. Humoral and cellular alloimmune mechanisms have been defined to varying degrees for the more acute insults, and thus the term “rejection” is an appropri-

ate descriptor (i.e., hyperacute rejection, acute cellular rejection, antibody-mediated rejection). However, the pathogenetic mechanisms underlying chronic forms of allograft dysfunction are less clear and both immunologic and nonimmunologic insults have been implicated. Although still part of the transplant lexicon, the term “chronic rejection” is misleading because it oversimplifies both the mechanism and the spectrum of phenotypes that characterize long-term allograft impairment. The term *chronic lung allograft dysfunction* (CLAD) is emerging as a preferred descriptor, comprising the most commonly encountered form, BOS, as well as newly recognized variants such as *restrictive allograft syndrome*. The various forms of rejection and CLAD are described in detail in the following sections. Features of the two most commonly encountered entities—acute cellular rejection and BOS—are summarized in Table 106-5.

Hyperacute Rejection

Hyperacute rejection is a rare but highly lethal complication mediated by preformed antibodies of recipient origin directed against HLA antigens contained in donor tissue. The pulmonary microvascular endothelium is the principal target, leading to complement- and neutrophil-mediated damage and widespread deposition of platelet/fibrin thrombi.¹⁴² Hyperacute rejection becomes clinically manifest within minutes to hours of establishing perfusion to the freshly implanted lung. The allograft appears dusky, mottled, and grossly edematous on direct inspection and densely opacified on chest radiograph. Reflecting the severity of pulmonary edema, copious amounts of pink, frothy edema fluid often are produced by the allograft and must be frequently suctioned from the endotracheal tube. Profound graft dysfunction and hemodynamic instability ensue. Four of the five cases reported in the literature resulted in death.¹⁴³ The one surviving patient was successfully managed with a combination of plasmapheresis, antithymocyte globulin, and cyclophosphamide.¹⁴⁴ Routine screening of all lung transplant candidates for preformed anti-HLA antibodies and either avoidance of donors with the targeted antigens or prospective cross-matching before transplantation have proved to be highly effective in minimizing the risk of hyperacute rejection.

Acute Cellular Rejection

Frequent surveillance of the allograft by transbronchial biopsy has demonstrated that most transplant recipients experience at least one episode of acute cellular rejection in the first year.⁵⁷ Beyond this initial period, the incidence of acute cellular rejection declines considerably. Risk factors for development of acute rejection remain poorly defined. Data are conflicting on whether the degree of HLA discordance between donor and recipient represents a risk factor.^{57,145,146} Polymorphisms in Toll-like receptor 4 that down-regulate recipient innate immune responsiveness are associated with a lower incidence of acute cellular rejection.¹⁴⁵

Episodes of acute cellular rejection may be clinically silent in up to 40% of cases.⁵⁷ When present, clinical manifestations are nonspecific and include malaise, low-grade fever, dyspnea, cough, and leukocytosis. Radiographic opacities (eFig. 106-2), a decline in arterial oxygenation at

Table 106-5 Features of Acute Cellular Rejection and Bronchiolitis Obliterans Syndrome (BOS)

Feature	Acute Cellular Rejection	BOS
Onset after transplant	Days to months; less common beyond the first year	Beyond first year
Risk factors	Uncertain	Acute rejection, lymphocytic bronchiolitis, community respiratory viruses, primary graft dysfunction, silent aspiration, CMV pneumonitis, airways colonization with <i>Aspergillus</i> or <i>Pseudomonas</i> species
Histology	Perivascular lymphocytic infiltrates	Bronchiolar submucosal inflammation and fibrosis; luminal obliteration
Signs and symptoms	Low-grade fever, dyspnea, cough, impaired oxygenation, leukocytosis	Dyspnea, chronic cough, recurrent bouts of purulent bronchitis
Chest radiograph	Alveolar or interstitial opacities, pleural effusions	Clear lung fields (may show hyperinflation)
High-resolution CT	Ground-glass or alveolar opacities, interlobular septal thickening	Tree-in-bud opacities, bronchiectasis, air trapping
Pulmonary function testing	Proportional decline in FEV ₁ and FVC	Disproportionate decline in FEV ₁ with worsening obstructive pattern
Yield of transbronchial biopsy	High	Low
Treatment	High-dose corticosteroids	Uncertain: azithromycin is a popular but unproven option
Outcome	Favorable response to treatment	Poor response to treatment; progressive allograft dysfunction in many cases

rest or with exercise, and an abrupt fall of greater than 10% in spirometric values are important clues to the possible presence of rejection, but similar findings accompany bouts of infection.

Reliance on clinical and radiographic criteria alone runs the risk of misdiagnosis and needless augmentation of immunosuppression. Transbronchial lung biopsy represents the “gold standard” for diagnosis of acute cellular rejection. The procedure is safe, can be performed in serial fashion over time, and has a high sensitivity and specificity. The histologic hallmark is the presence of perivascular lymphocytic infiltrates that, in more severe cases, spill over into the adjacent interstitium and alveolar air spaces. Lymphocytic bronchiolitis may accompany the parenchymal involvement or may be an independent feature. A histologic classification system has been universally adopted to grade the severity of acute cellular rejection (Table 106-6).¹⁴⁷

Conventional treatment consists of a 3-day pulse of intravenous Solu-Medrol at a daily dose of 15 mg/kg. In most cases, this results in rapid improvement in symptoms, pulmonary function, and radiographic abnormalities, but follow-up biopsies show histologic evidence of persistent rejection in 30% of patients with prior mild (A2) acute rejection and 44% of patients with prior moderate (A3) acute rejection.¹⁴⁸ Asymptomatic and functionally stable patients with minimal (A1) rejection have typically been observed without treatment, but data demonstrating progression to a higher grade of acute rejection in one quarter of cases and an increased risk of developing BOS have challenged this approach.¹⁴⁹ A variety of modalities have been employed for refractory or recurrent acute rejection including antilymphocyte antibody preparations and *photopheresis*, an immunomodulatory treatment using leukapheresis to collect *white blood cells* (WBCs), which are then treated with an ultraviolet light sensitizer, exposed to ultraviolet light, and returned to the body where they suppress T-cell function.

Table 106-6 Histologic Grading System for Acute Cellular Rejection

Grade	Description
0 (none)	Normal pulmonary parenchyma
1 (minimal)	Scattered, infrequent perivascular mononuclear infiltrates
2 (mild)	Frequent perivascular mononuclear infiltrates surrounding venules and arterioles; readily recognizable at low magnification
3 (moderate)	Easily recognizable cuffing of venules and arterioles by dense perivascular mononuclear cell infiltrates, with extension of the inflammatory cell infiltrate into perivascular and peribronchiolar alveolar septa and air spaces
4 (severe)	Diffuse perivascular, interstitial, and air space infiltrates of mononuclear cells with prominent alveolar pneumocyte damage and endothelialitis

From Stewart S, Fishbein MC, Snell GI, et al: Revision of the 1996 working formulation for the standardization of nomenclature in the diagnosis of lung rejection. *J Heart Lung Transplant* 26:1229–1242, 2007.

Acute Antibody-Mediated Rejection

There is emerging evidence in support of a second form of acute rejection, mediated by donor-specific anti-HLA allo-antibodies that develop *de novo* following transplantation.^{150,151} The clinical presentation can be indistinguishable from acute cellular rejection, with dyspnea, hypoxemia, and diffuse radiographic opacities. Hemoptysis should raise suspicion of this entity, but it is present in only 25% of cases.¹⁵⁰ The suggested diagnostic criteria for acute antibody-mediated rejection are (1) presence of circulating donor-specific anti-HLA antibodies; (2) histopathologic evidence of capillaritis; and (3) detection of endothelial cell C4d deposition. Less than half of patients in the largest case series responded to corticosteroids alone; the addition of

plasmapheresis was beneficial in the majority of steroid-refractory cases.¹⁵⁰ Intravenous immunoglobulin and anti-CD20 monoclonal antibodies have also been used as adjunctive therapy.¹⁵¹

Bronchiolitis Obliterans Syndrome

Bronchiolitis obliterans, presumed to represent the consequences of “chronic rejection,” stands as the major impediment to long-term graft and patient survival. Bronchiolitis obliterans is a fibroproliferative process characterized by submucosal inflammation and fibrosis of the bronchiolar walls, ultimately leading to complete obliteration of the airway lumen. The functional consequence of this process is progressive and largely irreversible airflow obstruction. Because the characteristic histology is difficult to demonstrate by transbronchial lung biopsy, the FEV₁ has been adopted as an easily obtained diagnostic surrogate for histology, and the term *bronchiolitis obliterans syndrome* (BOS) has been applied to this functionally defined disorder (Table 106-7).¹⁵² Approximately 50% of transplant recipients develop BOS by 5 years and 75% by 10 years.¹ As originally conceived, BOS was defined as an otherwise unexplained and sustained fall in FEV₁ by at least 20% from posttransplant baseline. Concern that this definition might delay diagnosis beyond a stage amenable to treatment prompted

the more recent introduction of a BOS *O-potential* (BOS O-p) stage, defined as a decline in FEV₁ by 10% to 19% or in mean forced expiratory flow between 25% and 75% of the forced vital capacity (FEF_{25%-75%}) by at least 25%. The FEV₁ criterion for BOS O-p has proved to be a reasonable predictor of patients at risk for progression to more advanced BOS, with a positive predictive value of 60% for progression within 1 year and 80% for progression within 4 years.^{153,154} The positive predictive value of the FEV₁ criterion is lower in SLT recipients with native lung emphysema, likely because of the confounding impact of native lung hyperinflation on lung function.¹⁵⁴ Notably, the FEF_{25%-75%} criterion suffers from a low positive predictive value in all recipient populations and is of questionable clinical utility.^{153,154}

Acute cellular rejection and lymphocytic bronchiolitis have been consistently identified as major risk factors for development of BOS, supporting the view that BOS is a consequence of alloimmune injury.^{155,156} Whereas the risk of BOS appears to correlate with the severity and frequency of these immunologic insults, even minimal (A1) acute rejection is associated with an increased risk.^{149,157} Other possible immune-mediated risk factors include the presence of anti-HLA antibodies (particularly donor specific) and the development of anti-type V collagen antibodies.^{158,159} Non-immune factors may also be important in initiating or perpetuating injury, suggesting that BOS may represent the end result of a wide array of insults to the airway epithelium. These factors include CMV pneumonitis, community respiratory viral infections, airway colonization with *Aspergillus* or *Pseudomonas*, primary graft dysfunction, and gastroesophageal reflux with occult aspiration.^{98,156,160-164}

Although often viewed as a late complication, BOS presents within the first 2 years after transplant in one third to one half of cases (“early-onset BOS”).^{165,166} The decline in FEV₁ that heralds the onset of BOS may be either insidious or abrupt. Dyspnea, weight loss, cough, and recurrent bouts of purulent tracheobronchitis, with recovery of *P. aeruginosa* from sputum cultures, are characteristic clinical features. Although chest radiographs are usually unremarkable, high-resolution CT commonly reveals air trapping (eFig. 106-3 and Videos 106-2 and 106-3), tree-in-bud opacities, and/or bronchiectasis (Fig. 106-5). The natural history of BOS is highly variable; those with early or abrupt

Table 106-7 Grading System for Bronchiolitis Obliterans Syndrome

Stage	Spirometric Criteria
0	FEV ₁ >90% of baseline and FEF _{25%-75%} >75% of baseline
0-potential	FEV ₁ 81%–90% of baseline and/or FEF _{25%-75%} ≤75% of baseline
1	FEV ₁ 66%–80% of baseline
2	FEV ₁ 51%–65% of baseline
3	FEV ₁ ≤50% of baseline

FEF_{25%-75%}, mean forced expiratory flow between 25% and 75% of forced vital capacity; FEV₁, forced expiratory volume in 1 second.

onset generally experience more rapid decline in lung function and higher mortality.^{165,166} Median survival from diagnosis is 1.5 years and 2.5 years for those with early- and late-onset BOS, respectively.¹⁶⁵

A myriad of immunosuppressive strategies have been employed in the treatment of BOS, including use of conventional agents (e.g., pulse corticosteroids), inhaled cyclosporine, antilymphocyte antibodies, photopheresis, and total lymphoid irradiation, but consensus is lacking on the optimal approach.^{167,168} At best, immunosuppressive measures appear to slow the rate of decline rather than to arrest or reverse the process. More recently, azithromycin has emerged as a popular alternative, based on retrospective studies documenting short-term improvement in the FEV₁ in approximately 30% to 40% of patients with BOS treated with this agent.¹⁶⁹⁻¹⁷² In contrast to nonresponders, responders demonstrate higher pretreatment levels of BAL neutrophilia and a marked reduction in neutrophilia following initiation of therapy. This lends credence to the notion that the beneficial effects of macrolides relate in large part to their ability to suppress airway IL-8 production and neutrophil recruitment.^{170,171} Although still controversial, performance of surgical fundoplication to control gastroesophageal reflux has been associated with improvement in lung function in some patients with BOS.¹⁷³ Adjuvant measures to mobilize respiratory secretions and control bacterial infection of the airways—including chest percussion, flutter or acapella valve, and inhaled and systemic antibiotics—may be of benefit in patients with accompanying bronchiectasis. At this time, the only definitive treatment for advanced BOS is retransplantation.

The development of strategies to prevent BOS is an area of intense interest but, to date, little substantive progress. In recognition of the established link between acute rejection and BOS, most transplant centers routinely perform surveillance lung biopsies to detect and treat clinically silent acute rejection, but the impact of this strategy on risk of BOS remains uncertain.¹⁷⁴ Early identification of recipients with gastroesophageal reflux and aggressive correction with fundoplication may delay or prevent onset of BOS, but this remains a controversial strategy.¹⁷⁵ In a small randomized trial, the addition of inhaled cyclosporine to a conventional immunosuppressive regimen was associated with a dramatic reduction in the incidence of BOS, but a subsequent multicenter trial failed to demonstrate benefit.^{176,177} A small, single-center, randomized, placebo-controlled trial demonstrated that the prophylactic administration of azithromycin after transplantation improved BOS-free survival, but larger, multicenter studies will be required to corroborate these findings.¹⁷⁸ Finally, some centers have employed a strategy to screen for donor-specific antibodies and, if detected, treat with intravenous immunoglobulin and rituximab in the hope of reducing the subsequent risk of developing BOS.¹⁷⁹ Again, however, additional studies are required to assess the efficacy of this approach.

Other Forms of Chronic Lung Allograft Dysfunction

Several other overlapping forms of CLAD that are distinct from BOS have recently been described. Various terms “restrictive allograft syndrome,”^{180,181} “restrictive-CLAD,”¹⁸² and “acute fibrinoid organizing pneumonia,”¹⁸³ these enti-

ties share in common a restrictive physiology and the presence of interstitial, alveolar, or ground-glass opacities on chest CT scans. The histologic findings vary among the published reports and include diffuse alveolar damage, interstitial fibrosis, and acute fibrinoid organizing pneumonia. There is remarkable agreement among the various reports on one point—survival of these patients is considerably worse than that of recipients with the more commonly encountered BOS.

POSTTRANSPLANTATION LYMPHOPROLIFERATIVE DISORDER

Posttransplant lymphoproliferative disorder (PTLD) describes a spectrum of abnormal proliferative responses involving B cells in the majority of cases and ranging from benign polyclonal hyperplasia to malignant lymphomas. In approximately 90% of cases, *Epstein-Barr virus* (EBV) is the stimulus for B-cell proliferation, which proceeds in an unchecked fashion due to the muted cytotoxic T-cell response in the immunosuppressed host. EBV-naïve recipients who acquire primary infection at the time of organ transplantation are at greatest risk of developing PTLD.¹⁸⁴ A higher intensity of immunosuppression and, in particular, the use of antilymphocyte antibody preparations have also been implicated as risk factors.

Among the myriad neoplasms that arise following lung transplantation, PTLD is second in frequency only to non-melanoma skin cancers, with an incidence of approximately 5%.¹⁸⁵ The risk of developing PTLD is greatest within the first posttransplantation year, though up to half of all cases are seen beyond this point. The majority of early-onset cases involve the allograft, typically presenting as one or more pulmonary nodules that may be accompanied by mediastinal adenopathy (Fig. 106-6). In contrast, beyond the first year, intra-abdominal and disseminated forms of disease predominate.¹⁸⁵

The diagnosis of PTLD is most firmly established by tissue biopsy, though fine-needle aspiration may occasionally

Figure 106-6 Posttransplantation lymphoproliferative disorder. CT scan demonstrates multiple nodules and masses, proven on biopsy to represent a high-grade B-cell lymphoma. In situ hybridization studies revealed the presence of Epstein-Barr virus RNA.

yield sufficient material to make a cytologic diagnosis. Care must be exercised in interpreting transbronchial lung biopsies because the aggregates of lymphocytes associated with acute cellular rejection can appear similar to foci of PTLD on these small tissue specimens. Demonstration of the presence of EBV-infected cells by in situ hybridization or immunohistochemical staining can help to confirm a diagnosis in difficult cases. Determination of EBV viral load in the peripheral blood using DNA amplification techniques has been touted as an ancillary diagnostic tool. Preliminary studies involving adult lung transplant recipients suggest that an elevated viral load correlates with the presence of PTLD with a high degree of specificity (i.e., low false-positive rate), but the sensitivity is as low as 39%.^{186,187} Additional studies employing uniform assay techniques and threshold values for positive results are required before conclusions can be drawn about the clinical utility of this test.

Initial treatment of PTLD involves reduction in the magnitude of immunosuppression to permit partial restoration of host cellular immunity against EBV. Regression of tumor is seen in up to two thirds of cases, but there is an attendant risk of precipitating acute or chronic rejection and patients must be monitored closely.¹⁸⁸ For patients who fail to achieve a complete remission, cannot tolerate reduced immunosuppression, or have rapidly progressive disease, immunotherapy with anti-CD20 monoclonal antibodies (rituximab) has emerged as the preferred option. Use of this agent in the solid organ transplant population is generally well tolerated and associated with a complete response rate of 60%.¹⁸⁹ In contrast, experience with standard chemotherapy has been poor, with up to one quarter of patients succumbing to treatment-related complications.¹⁸⁹ There is no proven role for antiviral therapy in the setting of established PTLD, though there is suggestive evidence that the prophylactic use of antiviral agents may reduce the subsequent risk of developing PTLD.¹⁹⁰

LUNG CANCER

The development of lung cancer following lung transplantation has been reported almost exclusively in patients with underlying COPD or pulmonary fibrosis, the majority of whom have had significant prior smoking histories. The reported incidence of lung cancer following transplantation is 2% to 6% in patients with COPD and 3% to 4% in patients with pulmonary fibrosis.¹⁹¹⁻¹⁹⁴ Data are conflicting on whether transplantation confers an increased likelihood of developing this form of cancer or whether the incidence is comparable with that of the general population with similar risk factors. Lung cancer most commonly arises in the native lung of SLT recipients. Less commonly, a previously unsuspected cancer may be incidentally detected in the explanted lung removed at the time of transplantation and may then recur in the allograft or in distant sites. A high rate of recurrence has also been documented in instances when lung transplantation has been performed as definitive treatment for underlying bronchioalveolar carcinoma.⁴ Finally, there are rare reports of lung cancer of donor origin transmitted to the recipient.¹⁹⁵

Lung cancer in the transplant recipient often progresses at a rapid pace, potentially leading to initial confusion with an infectious process (Fig. 106-7).¹⁹¹ This aggressive behavior may reflect loss of antitumor immune surveillance in the immunosuppressed host or may be due to a more specific effect of cyclosporine in promoting tumor growth.¹⁹⁶ Overall prognosis is poor but should not preclude attempts at curative resection in the rare instances in which early-stage disease is encountered.

RECURRENCE OF PRIMARY DISEASE

A number of primary disorders have been documented to recur in the allograft following transplantation.¹⁹⁷ Although

Figure 106-7 Bronchogenic carcinoma arising in the native lung. The patient had undergone a left single-lung transplant for idiopathic pulmonary fibrosis (IPF). **A**, Chest radiograph demonstrates slight fullness in the infrahilar region of the native right lung (arrow). **B**, Repeat chest radiograph only 2 months later demonstrates marked enlargement of the right infrahilar mass, as well as an increase in adjacent interstitial opacities. This proved to be a right lower lobe squamous cell lung cancer with associated lymphangitic spread.

accurate figures are not available, sarcoidosis appears to have the greatest propensity to do so. Recurrence of sarcoidosis is typically asymptomatic and marked by incidental recovery of noncaseating granulomas on bronchoscopy and occasionally by the presence of micronodular opacities in the upper lobes on CT scan. Cases of recurrent lymphangioleiomyomatosis have also been reported. The abnormal smooth muscle cells found in the allograft are of recipient origin, suggesting that the mechanism of recurrence involves migration or metastasis from an extrapulmonary site.¹⁹⁸ Other diseases for which recurrence has been reported include Langerhans cell histiocytosis, desquamate interstitial pneumonia, and diffuse panbronchiolitis.

Recurrence of emphysema in the allograft was documented in a recipient 11 years after transplantation for α_1 -antitrypsin deficiency.¹⁹⁹ The patient had resumed smoking and this was presumed to play a central role in accelerating the recurrence of disease. BAL fluid obtained after disease recurrence demonstrated free elastase activity, suggesting that the endogenous antiprotease defenses had been overwhelmed. These observations highlight the need for α_1 -antitrypsin-deficient transplant recipients to abstain from smoking but do not provide justification for the routine use of enzyme replacement therapy following transplantation.

As previously mentioned, attempts to utilize lung transplantation as a definitive treatment for bronchioalveolar carcinoma resulted in recurrence rates of approximately 50%, leading the vast majority of centers to abandon this approach.⁴

RETRANSPLANTATION

Retransplantation has been utilized as a salvage technique for refractory graft failure. Outcomes following early, emergent retransplantation for primary graft dysfunction are poor, and consequently, use of this intervention in this setting is discouraged.^{94,200} In contrast, retransplantation of carefully selected patients with chronic graft failure due to BOS results in survival rates that approach that of initial transplantation. The new allocation system introduced in the United States assigns a high priority to candidates with BOS, on par with that afforded to patients with IPF. This has led to shortened waiting times and to a doubling in number of retransplant procedures performed annually.⁹⁴ Although the feasibility and reasonable success of retransplantation for BOS have been established, the issue of its appropriateness in the setting of severe organ shortages remains a vexing ethical dilemma.

FUTURE DIRECTIONS

Since its introduction in 1963, lung transplantation has evolved from a heroic surgical therapy to a standard option for select patients with advanced lung disease. Nonetheless, major hurdles must yet be overcome in order to facilitate wider applicability of lung transplantation and more enduring results. The donor organ supply must be expanded to meet demand. More effective and less toxic immunosuppressive strategies must be developed to prevent graft loss

from chronic immunologic injury. An improved understanding of BOS and other forms of chronic allograft dysfunction is required in order to develop strategies to treat injuries of the transplanted lung in a targeted fashion.

Increased utilization of ex vivo lung perfusion for assessment and treatment may offer a partial solution to enhancing the number, quality, and durability of lung allografts. The ultimate solution to many of the current impediments will likely come with advances in gene therapy, stem cell therapy, and tissue engineering. Advances in immunologic manipulation of the recipient and immunologic modulation of the organs to look more like “self” will ultimately one day bring us closer to a state of immune tolerance (i.e., permanent graft acceptance in the absence of chronically administered immunosuppressive agents). It is only through these basic research initiatives that lung transplantation will truly fulfill its potential as a safe, effective, and durable treatment option.

Key Points

- Lung transplantation is a therapeutic option for a broad spectrum of advanced nonmalignant disorders of the airways, lung parenchyma, and pulmonary vasculature. The most common indications are COPD, idiopathic pulmonary fibrosis, and cystic fibrosis.
- Single-lung and bilateral-lung transplants account for 97% of all procedures; heart-lung transplantation and living donor bilobar transplantation account for the rest.
- The lung allocation system now utilized in the United States grants priority to patients with the greatest predicted “net transplant benefit”—the difference between predicted 1-year survival with versus without transplantation.
- One-, 5-, and 10-year survival rates following transplantation are 82%, 55%, and 33%, respectively.
- Common early complications include primary graft dysfunction due to ischemia-reperfusion injury, bronchial anastomotic stenosis, and bacterial pneumonias.
- Infection rates among lung transplant recipients are several fold higher than among recipients of other solid organs, presumably due to exposure of the allograft to microorganisms via inhalation and aspiration and the higher level of immunosuppression in the lung transplant patients.
- Acute cellular rejection, characterized by perivascular lymphocytic infiltration, is commonly encountered in the first year. It usually responds to high-dose corticosteroid therapy but is a major risk factor for subsequent development of bronchiolitis obliterans syndrome.
- The major limitation to long-term allograft function and patient survival is bronchiolitis obliterans, characterized histologically by fibroproliferative obliteration of the small airways and physiologically by progressive airflow obstruction.
- Newer approaches include ex vivo lung perfusion to assess lung function and perhaps to recondition lungs before transplantation and bridging recipients using extracorporeal artificial lungs, either with pumps or without, until transplantation.

eFIGURE IMAGE GALLERY

eFigure 106-1 Posttransplant ischemic anastomotic bronchostenosis. A–D, Axial chest dynamic expiratory CT (performed during a forced vital capacity maneuver) displayed in lung windows in a bilateral lung transplant recipient shows narrowing of the bronchus intermedius (*arrow*) associated with extensive hyperlucency and increased volume throughout the right lower lobe (*arrowheads*), reflecting air trapping in the lung subtended by the stenotic airway. (Courtesy Michael Gotway, MD.)

eFigure 106-2 Acute cellular rejection in a lung transplant recipient: high-resolution chest CT findings. **A** and **B**, Axial high-resolution CT displayed in lung windows shows smooth interlobular septal thickening (*arrowheads*) in the transplanted right lung and right pleural effusion (*) detected at the time of diagnosis of biopsy-proven acute cellular rejection; these findings are markedly reduced following augmentation of immunosuppression (**B**). The findings of interlobular septal thickening, volume loss, and pleural effusion are not specific for acute cellular rejection, although that diagnosis is uncommon when these high-resolution CT findings are absent. (Courtesy Michael Gotway, MD.)

Figure 106-3 Bronchiolitis obliterans syndrome: high-resolution CT findings in a bilateral lung transplant recipient. A–C and [Video 106-2](#), Axial inspiratory high-resolution CT shows minimal findings, with only slightly inhomogeneous lung opacity best seen in the bases (C). D–F and [Video 106-3](#), Axial dynamic expiratory high-resolution CT (performed during a forced vital capacity maneuver) shows interval development of extensive, bilateral inhomogeneous lung opacity—the lighter regions reflect normal, collapsing lung at expiratory imaging, whereas the darker areas (arrowheads) represent air trapping due to small airway obstruction, reflecting bronchiolitis obliterans. (Courtesy Michael Gotway, MD.)

GLOSSARY OF TERMS AND STANDARD SYMBOLS

I. PRIMARY AND QUALIFYING SYMBOLS

GENERAL

P	Pressure (Includes also <i>partial</i> pressure of a gas in a mixture of gases or in blood.)
L	Lung
W	Chest wall
RS	Respiratory system
Pl	Pleura

VENTILATION

V	Volume of gas
\dot{V}	Flow of gas
I	Inspired
E	Expired
A	Alveolar
T	Tidal
ET	End-tidal
D	Dead space
STPD	<i>Standard Conditions:</i> standard temperature (0°C), barometric pressure (760 mm Hg), and dry.
BTPS	<i>Body Conditions:</i> body temperature and ambient pressure, saturated with water vapor at these conditions.
ATPS	<i>Ambient Conditions:</i> ambient temperature and pressure, saturated with water vapor at these conditions.

GAS EXCHANGE–BLOOD FLOW

Q	Volume of blood
Q	Flow of blood
F	Fractional concentration of gas
C	Concentration in blood
S	Saturation in blood
b	Blood, in general
a	Arterial blood
v	Venous blood
\bar{v}	Mixed venous blood
c	Capillary blood
c'	Pulmonary end-capillary blood

II. VENTILATION AND LUNG MECHANICS

STATIC LUNG VOLUMES

VC	<i>Vital Capacity:</i> The maximum volume of gas that can be exhaled after fully inflating the lungs.
FRC	<i>Functional Residual Capacity:</i> The volume of gas remaining in the lungs at the end of quiet expiration.
TLC	<i>Total Lung Capacity:</i> The volume of gas in the lungs after a maximum inspiration.
RV	<i>Residual Volume:</i> The volume of gas remaining in the lungs after a maximum exhalation.
IC	<i>Inspiratory Capacity:</i> The volume of gas that can be inhaled from resting end-expiration (FRC) to full inflation (TLC).
ERV	<i>Expiratory Reserve Volume:</i> The volume of gas that can be exhaled from resting end-expiration (FRC) to full exhalation (RV).
IRV	<i>Inspiratory Reserve Volume:</i> The volume of gas that can be inhaled from resting end-inspiration to full inflation (TLC).

DESCRIPTORS OF FORCED BREATHING MANEUVERS

FVC	<i>Forced Vital Capacity:</i> The volume of gas that can be forcibly exhaled after fully inflating the lungs.
FEV _t	<i>Timed Forced Expiratory Volume:</i> The volume of gas exhaled at a specified time after beginning the forced vital capacity maneuver. For example, FEV ₁ = forced expiratory volume in 1 second.
FEV _t /FVC	<i>Ratio of Timed Expiratory Volume to Forced Vital Capacity:</i> For example, FEV ₁ /FVC, usually expressed as a percentage.

FEF _x	<i>Specified Forced Expiratory Flow:</i> The forced expiratory flow rate during a specified portion of the forced vital capacity. For example, FEF _{200–1200 mL} = forced expiratory flow rate between 200 and 1200 mL of the forced vital capacity; FEF _{25%–75%} = forced expiratory flow rate between 25% and 75% of the forced vital capacity.
$\dot{V}_{\max_x\%}$	<i>Specified Maximum Expiratory Flow:</i> The instantaneous expiratory flow rate when <i>x</i> percent of the forced vital capacity has been exhaled. For example, $\dot{V}_{\max_{50\%}}$ = maximum expiratory flow rate at 50% of the forced vital capacity.
MVV	<i>Maximum Voluntary Ventilation:</i> Volume of gas exhaled while making maximum breathing efforts during a certain time interval (often 12 seconds).
VR	<i>Ventilatory Reserve:</i> The difference between ventilatory capacity during maximum exercise (estimated as MVV or calculated from FEV ₁) and minute ventilation at peak exercise; VR, which is also known as <i>breathing reserve</i> , represents the potential for further increase in ventilation during maximum (or peak) exercise.
Pr _{max}	<i>Maximum Inspiratory Pressure:</i> The maximum pressure generated by the respiratory muscles during an attempted inspiration.
PE _{max}	<i>Maximum Expiratory Pressure:</i> The maximum pressure generated by the respiratory muscles during an attempted exhalation.

DESCRIPTORS OF VENTILATION

f	<i>Respiratory Frequency:</i> The number of breaths during 1 minute.
V _T	<i>Tidal Volume:</i> The volume of gas inspired or expired during each breath.
\dot{V}_E	<i>Expired Ventilation:</i> The volume of gas (BTPS), usually measured at the mouth, exhaled during 1 minute.
\dot{V}_I	<i>Inspired Ventilation:</i> The volume of gas (BTPS), measured or calculated, inhaled during 1 minute.
\dot{V}_A	<i>Alveolar Ventilation:</i> The volume of gas (BTPS), exhaled from the lungs during 1 minute, that contributed to gas exchange; calculated as expired ventilation minus dead space ventilation.

\dot{V}_D	<i>Dead Space Ventilation:</i> The volume of gas (BTPS), exhaled from the lungs during 1 minute, that did not contribute to gas exchange; also known as <i>wasted ventilation</i> . Calculated from the equation $\dot{V}_D = \dot{V}_E \frac{P_{aCO_2} - P_{ECO_2}}{P_{aCO_2} - P_{iCO_2}}$ where P _{aCO₂} , P _{ECO₂} , and P _{iCO₂} are the partial pressures of CO ₂ in arterial blood, mixed expired gas, and inspired gas, respectively.
V _D	<i>Dead Space Volume:</i> The volume of the physiologic dead space; calculated as \dot{V}_D/f .
V _D /V _T	<i>Ratio of Dead Space to Tidal Volume:</i> The proportion, usually expressed as a percentage, of each breath that does not contribute to CO ₂ removal (i.e., the proportion of each breath that is wasted).
VE	<i>Ventilatory Equivalent:</i> The minute ventilation required for each liter of gas exchanged, either O ₂ or CO ₂ ; used as a measure of the efficiency of the lungs as a gas exchanger. For O ₂ : $VE_{O_2} = \frac{\dot{V}_E \text{ (BTPS)}}{\dot{V}_{O_2} \text{ (STPD)}}$

VOLUME-PRESSURE RELATIONSHIPS

C	<i>Compliance:</i> General symbol for compliance, or the ratio of volume change of the structure per unit change in applied pressure across the structure.
CL	<i>Lung Compliance:</i> The volume change of the lung divided by the difference between alveolar pressure (Palv) and pleural pressure (Ppl), which is also known as the transpulmonary pressure (PL).
CW	<i>Chest Wall Compliance:</i> The volume change of the chest wall divided by the difference between pleural pressure (Ppl) and body surface pressure (Pbs), which is also known as the transthoracic pressure (PW).
Crs	<i>Respiratory System Compliance:</i> The volume change of the lung and chest wall divided by the difference between alveolar pressure (Palv) and body surface pressure (Pbs), or transpulmonary pressure (PL) plus transthoracic pressure (PW).
Cdyn	<i>Dynamic Compliance:</i> Value for compliance based on measurements made during uninterrupted breathing.

Cst	<i>Static Compliance:</i> Value for compliance based on measurements made during periods of no airflow.	RQ	<i>Respiratory Quotient:</i> The ratio of $\dot{V}CO_2$ to $\dot{V}O_2$ during steady-state metabolic activity.
C/VL	<i>Specific Compliance:</i> Value for compliance divided by the lung volume at which it was measured, usually functional residual capacity.	RER	<i>Respiratory Exchange Ratio:</i> The ratio of $\dot{V}CO_2$ to $\dot{V}O_2$, as in RQ, but also including the influence of transient changes in body stores of respiratory gases.

FLOW-PRESSURE RELATIONSHIPS

R	<i>Resistance:</i> General symbol for frictional resistance, or the pressure difference divided by flow.
RAW	<i>Airway Resistance:</i> Resistance calculated from pressure difference between airway opening (Pao) and alveoli (Palv) divided by the airflow.
RL	<i>Total Pulmonary Resistance:</i> Resistance calculated by dividing flow-dependent transpulmonary pressure by airflow at the mouth.
GAW	<i>Airway Conductance:</i> The reciprocal of RAW.
GAW/VL	<i>Specific Conductance:</i> Value for airway conductance divided by the lung volume at which it was measured.

III. GAS EXCHANGE

BLOOD

Examples shown are for O₂; other gases (e.g., CO₂, N₂, CO) or other sites (e.g., \bar{v} , c') can be substituted when appropriate.

PO ₂	<i>Partial Pressure of O₂:</i> General designation (expressed in mm Hg); source usually specified (e.g., arterial PO ₂ or PaO ₂).	DL
SO ₂	<i>Blood Saturation:</i> General designation (expressed as a percentage); source usually specified (e.g., arterial SO ₂ or SaO ₂).	DM
CO ₂	<i>Oxygen Content:</i> General designation (expressed in mL/dL); source usually specified (e.g., arterial CO ₂).	1/DL
$\dot{V}O_2$	<i>Oxygen Consumption:</i> The volume of O ₂ (STPD) utilized by the body during 1 minute; usually calculated as the amount of O ₂ extracted from inspired gas.	
$\dot{V}O_{2max}$	<i>Maximum Oxygen Consumption:</i> The maximal volume of O ₂ (STPD) that can be utilized by the body during 1 minute of maximally attainable exercise.	
$\dot{V}CO_2$	<i>Carbon Dioxide Output:</i> The volume of CO ₂ (STPD) produced by the body during 1 minute; usually calculated as the amount of CO ₂ added to exhaled gas.	DL/VA

GAS TO BLOOD

(A-a)PO ₂	<i>Alveolar-Arterial PO₂ Difference:</i> The difference in PO ₂ between mean alveolar gas and arterial blood (expressed in mm Hg).
	<i>Alveolar Gas Equation:</i> Often used to calculate mean alveolar PO ₂ (PAO ₂):

$$PAO_2 = PIO_2 - \frac{PACO_2}{R}$$

where PIO₂ is the PO₂ of inspired gas; PACO₂ is the alveolar PCO₂ (usually assumed to equal arterial PCO₂); and R is the respiratory exchange ratio. Because of some assumptions, this equation is an approximation. For calculating the exact PAO₂, an additional term is needed, where FIO₂ is the fractional concentration of O₂ in inspired gas.

$$PAO_2 = PIO_2 - \frac{PACO_2}{R} + \left[PACO_2 \times FIO_2 \times \frac{(1-R)}{R} \right]$$

Diffusing Capacity of the Lung: Expressed as the volume of gas transferred per minute per unit of alveolar-capillary pressure difference for the gas used, which is usually specified (e.g., DL_{CO} or DL_{O₂}).

Diffusing Capacity of the Alveolocapillary Membrane.

Total Resistance to Diffusion: The sum of the resistance to diffusion of the test gas across the alveolocapillary membrane (1/DM) and the resistance to diffusion within the red blood cells attributable to the chemical reaction between the test gas and hemoglobin (1/θVC). These relationships are expressed by the Roughton-Forster equation:

$$\frac{1}{DL} = \frac{1}{DM} + \frac{1}{\theta VC}$$

Diffusion per Unit of Alveolar Volume: The value of DL (STPD) divided by VA (BTPS), both measured in the same breathing maneuver.

IV. HEMODYNAMIC DESCRIPTORS

\dot{Q}_T	<i>Cardiac Output:</i> The total output of the left ventricle during one minute.
\dot{Q}_S	<i>Pulmonary Shunt Flow:</i> The total amount of blood per minute perfusing completely nonventilated gas-exchange units; hence, blood that does not come in contact with inspired gas and does not contribute to oxygen uptake. Often called the <i>right-to-left shunt</i> , but this term also includes intracardiac shunts.
\dot{Q}_S/\dot{Q}_T	<p><i>Pulmonary Shunt Fraction:</i> The total pulmonary shunt (\dot{Q}_S), or venous admixture, expressed as a percentage of total cardiac output (\dot{Q}_T) according to the equation:</p> $\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{Cc'O_2 - CaO_2}{Cc'O_2 - C\bar{V}O_2} \times 100$ <p>where $Cc'O_2$ is the O_2 content of end-capillary blood; CaO_2 is the O_2 content of arterial blood; and $C\bar{V}O_2$ is the O_2 content of mixed venous blood. While breathing 100% O_2 (and sampling systemic arterial blood, not end-capillary blood), \dot{Q}_S/\dot{Q}_T is a measure of right-to-left shunting of blood.</p>
PPA	<i>Pulmonary Artery Pressure:</i> The pressure—systolic, diastolic, or mean—measured in the pulmonary artery.
PLA	<i>Left Atrial Pressure:</i> The pressure, usually mean, measured in the left atrium.
Pcap	<p><i>Pulmonary Capillary Pressure:</i> The mean pressure in the pulmonary capillaries, sometimes abbreviated P_c, which cannot be measured directly in humans but is frequently estimated by the equation:</p> $P_{cap} = PLA + 0.4 (PPA - PLA)$
PPW	<i>Pulmonary Wedge Pressure:</i> The mean pressure measured by the pulmonary artery occlusion technique, which provides an estimate of the postcapillary, or pulmonary venous, pressure.
PVR	<p><i>Pulmonary Vascular Resistance:</i> The resistance to blood flow through the lungs; a calculated value from the equation:</p> $PVR = \frac{PPA - PLA}{\dot{Q}_T}$ <p>in which PPW is often used to approximate PLA.</p>

V. OTHER USEFUL TERMS AND EQUATIONS

PEEP	<i>Positive End-Expiratory Pressure:</i> The condition in which the pressure in the lungs at the end of expiration is positive (i.e., higher than atmospheric). Usually applied externally by ventilator adjustments; when PEEP results from failure to exhale fully at the end of expiration, it is called <i>intrinsic</i> (PEEPi).
$P_{0.1}$	<i>Mouth Occlusion Pressure:</i> The pressure measured in the mouth during the first 0.1 second of attempted inspiration after the airway is temporarily occluded while the subject is breathing. An estimate of the central drive to breathe.
T_i/T_T	<p><i>Duty Cycle:</i> The ratio of the duration of inspiration (T_i) to the duration of inspiration and expiration (T_T), a reflection of respiratory timing.</p> <p><i>Henderson-Hasselbalch Equation:</i> Useful for calculating any one of three variables, pH, HCO_3^-, or H_2CO_3, when two of them are known:</p> $pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]}$ <p>where pK, the dissociation constant, is 6.10 for plasma at 37°C; $[HCO_3^-]$ is the concentration of bicarbonate in plasma; and $[H_2CO_3]$ is the concentration of carbonic acid in plasma (both in mol/L). The equation can be rearranged by using PCO_2 (in mm Hg) and its solubility in plasma so that</p> $pH = pK + \log \frac{[HCO_3^-]}{[PCO_2 \times 0.0301]}$ <p><i>Starling Equation:</i> Net fluid exchange (J_v) across the microvascular barrier in the lungs:</p> $J_v = L_p S [(P_c - P_i) - \sigma d (\pi_c - \pi_i)]$ <p>where L_p is the hydraulic conductivity (“permeability”); S is the surface area; P_c is the microvascular hydrostatic pressure; P_i is the perimicrovascular hydrostatic pressure; σd is the osmotic reflection coefficient; π_c is the microvascular colloid osmotic pressure; and π_i is the perimicrovascular colloid osmotic pressure.</p>

 metastatic malignant tumors, 981–990
 rare primary tumors, 965–980
- obstructive diseases
 asthma, clinical diagnosis and management, 731–750
 asthma, genetics in, 786–806
 asthma, pathogenesis and phenotypes, 713–730
 bronchiectasis, 853–876
 bronchiolitis, 897–911
 chronic obstructive pulmonary disease (COPD), clinical diagnosis and management, 767–785
 chronic obstructive pulmonary disease (COPD), genetics in, 786–806
 chronic obstructive pulmonary disease (COPD), pathogenesis and natural history, 751–766
 cystic fibrosis (CF), 822–852
 intrathoracic airway disorders, 897–911
 smoking hazards and cessation, 807–821
 upper airway disorders, 877–896
- pleura disorders
 chylothorax, 1439–1460
 fibrothorax, 1439–1460
 hemothorax, 1439–1460
 infections, 1425–1438
 pleural effusion (PE), 1396–1424
 pneumothorax, 1439–1460
 tumors, 1461–1477
- pulmonary circulation disorders
 pulmonary arterial hypertension (PAH), 1031–1049
 pulmonary edema, 1096–1117
 pulmonary hypertension due to lung disease (PH-LD), 1050–1065
 pulmonary thromboembolism, 1001–1030
 pulmonary vascular abnormalities, 1081–1095
 pulmonary vasculitis, 1066–1080
- respiratory failure management
 acute hypoxemic respiratory failure, 1740–1760
 acute respiratory distress syndrome (ARDS), 1740–1760
 acute ventilatory failure, 1723–1739
 end-of-life care, 1807–1820
 extracorporeal membrane oxygenation (ECMO), 1794–1806
 pulmonary rehabilitation, 1821–1831
 transplantation, lung, 1832–1849
 ventilation, mechanical, 1761–1777
 ventilation, non-invasive, 1778–1793
- symptom management
 chest pain, 515–526
 cough, 497–514
 dyspnea, 485–496

- Clinical trials/studies, named
 BEOCOPD cohort study, 798–799
 Cancer Prevention Study II, 935
 Collaborative Study on the Genetics of Asthma (CSGA), 788
 IMPROVE trial, 1078–1079
 International Study of Asthma and Allergies in Children (ISAAC) study, 714–715
 Multicenter Intrapleural Sepsis Trial (MIST) 1 study, 1426, 1426f
 National Emphysema Treatment Trial (NETT), 1822
 National Health and Nutrition Examination Survey (NHANES) III, 476
 National Lung Screening Trial, 935
 National Lung Screening Trial (NLST), 316–318, 935, 941
 Nocturnal Oxygen Therapy Trial (NOTT), 1827
 Perioperative ISSchemic Evaluation (POISE), 461
 Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, 1005–1006, 1010–1011
 Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis (PISA-PED) trials, 1010–1011
 Salmeterol Multicenter Asthma Research Trial (SMART), 742
